Abstract: Potentially toxic elements are persistent in the environment and plants have the ability to absorb and transfer them from soil in edible parts. The objectives of this study were to characterize the distribution of Cd and Pb in quinoa tissues and to investigate their accumulation and transfer from irrigated water in edible parts of quinoa. For the purpose of this study experiment and simulated pollution in the form of different metal concentration in water that was used for irrigation was designed. Distribution of metals in quinoa were determined and analyzed in seed formation and maturation stage. Bioaccumulation and translocation factors were calculated to characterize the efficiency of quinoa to absorb metals. The results of our study indicated that quinoa adopts potentially toxic metals from substrate but does not accumulate them. The potential of such a conclusion is useful for exploring the use of quinoa as lead and cadmium excluders.

Keywords: potentially toxic elements; water-to-plant transfer; bioaccumulation factor; translocation factor; metal excluders

1. Introduction

In numerous publications in recent decades, the term “heavy metals” is a group term for metals that are contaminants. The toxicity of a substance can only be defined if the relationship between dose and effect is known. This relationship is a characteristic of each substance and it is necessary to know this relationship when determining whether a substance is toxic or not. The term “Potentially Toxic Element(s)” (PTEs) can include uniform and comparative use, and meanings on the basis of more reliable characterization [1].

Potentially toxic elements (PTEs) are not susceptible to biodegradation, they are persistent in the environment and plants can absorb them from soil and accumulate them in edible parts. Consequently, PTEs can enter into the food chain, creating a risk to human health [2,3].

Cadmium (Cd) is extremely toxic at very low concentration for both plants and humans [4]. Toxic effects of cadmium in plants is reflected through its affinity for the thiol group as Cd can block functional groups of biomolecules, which results in the inhibition of enzyme activity of important plant metabolic processes, such as photosynthesis and respiration [5]. Since it belongs to the group of metals whose ions can rapidly be absorbed by plant roots, Cd is very mobile in soil and available to plants, and can easily be implemented into the food chain [6].

The toxic effect of lead (Pb) is more expressed at higher concentration and duration of exposure. These levels of Pb concentration in the plant affect germination, growth, photosynthesis, water regime,
mineral nutrition and enzyme activity [7,8]. Accumulation of Pb by plants has been reported in roots, shoots, leaves and seeds. However, the majority of absorbed Pb by plants resides in the root, having only small amounts translocated to the aerial parts of plants [8].

Despite their relatively low concentration in edible parts of plant, both Cd and Pb are reported as food contaminants and food agencies highlight their threat to human health [9]. The uptake, accumulation and translocation of toxic metals by plants can differ widely even across cultivars within the same species [10].

Quinoa (Chenopodium quinoa Will) is a pseudocereal originated in the Andean region of South America. This cereal has received an increased interest across Europe lately due to its high protein content and compositions of protein [11]. Because of its nutritional value (rich in protein, fat, dietary fiber and minerals) quinoa is applied in the production of bread, pasta and baby food [12]. The Food and Agriculture Organization declared 2013 to be the “International Year of Quinoa” [13].

In 1995, 61.0 tons of quinoa was exported from Peru; in 2014, global demand for quinoa was 60 times higher, so they exported 36,000 tons of quinoa [14].

Estimated high nutritional value in alternative cereals, including quinoa, is associated with their qualitative and quantitative composition of protein [15,16]. The content of protein in quinoa ranges in value from 12.1% to 14.5% [17,18], with the maximum content being up to 22.08% [19,20].

The bioaccumulation and translocation potentials of PTEs by plants grown on contaminated soil were studied on Plantago major L. [21], Triticum aestivum [22,23], 30 varieties of Brassica pekinensis L. [24], miscanthus [25,26] and 32 hybrid rice varieties [27]. Transfer of PTEs from water-to-plant were studied on 14 sunflower hybrids [28], two eucalypt hybrid clones [29], wheat and different vegetables [30].

In spite of some research characterizing accumulation and transfer of PTEs in crops, the literature search revealed that quinoa has not been a focus of such research, and so this was identified as a research gap by the authors of this paper. The objectives of this study were to characterize the distribution of Cd and Pb in quinoa tissues and to investigate accumulation and transfer of Cd and Pb from irrigated water in edible parts of quinoa.

2. Materials and Methods

2.1. Experimental Design

For the purpose of this experiment, plant growth chamber (FITOCLIMA 20000HP MI234INR00—Ingles, 20–25 °C, 12–15 h photoperiod, RH 60%) was used. Composition of Floradur B (Floragard, Germany) was: 70% of German white peat + 30% German black peat + lime + macro and micro elements (Mg, B, Cu, Mn, Mo, Fe and Zn) + wetting agent. A Superfine structure was used with a pH of 5.6 and a salt content of 0.8 g/l.

Such an experiment simulated pollution in the form of different metal concentrations in water that was used for irrigation. The experiment had 12 treatments with 5 simultaneous repetitions, leading to a total of 60 variations. Solutions for plant watering were made by dissolving salts of lead (Pb (CH₃COO)₂ × 3H₂O) and cadmium (3CdSO₄ × 8H₂O) in tap water.

During the entire duration of the experiment, soil moisture was maintained at level of 60% of the water retention capacity.

After 4 weeks, continuously to the end of the experiment, the following treatments were applied: I—tap water, II—5 mg/kg Pb, III—50 mg/kg Pb, IV—100 mg/kg Cd, V—5 mg/kg Pb and Cd, VI—50 mg/kg Cd, VII—100 mg/kg Cd, VIII—5 mg/kg Pb and Cd, IX—50 mg/kg Pb and Cd, X—100 mg/kg Pb and Cd, XI—100 mg/kg Pb and 5 mg/kg Cd, XII—5 mg/kg Pb and 100 mg/kg Cd (Table 1).

Grain formation was observed after 100 days and two plants from each treatment were harvested. After 20 days, maturation of grain was completed and the rest of the plants were harvested.
Table 1. Experimental design, applied treatments.

| Treatment Number | Treatment Applied |
|------------------|-------------------|
| I                | tap water         |
| II               | 5 mg/kg Pb        |
| III              | 50 mg/kg Pb       |
| IV               | 100 mg/kg Pb      |
| V                | 5 mg/kg Cd        |
| VI               | 50 mg/kg Cd       |
| VII              | 100 mg/kg Cd      |
| VIII             | 5 mg/kg Pb and Cd |
| IX               | 50 mg/kg Pb and Cd|
| X                | 100 mg/kg Pb and Cd|
| XI               | 100 mg/kg Pb and 5 mg/kg Cd |
| XII              | 5 mg/kg Pb and 100 mg/kg Cd |

2.2. Chemical Analysis

The first set of harvested plants were separated into root, shoot, leaf and seed; while the second set of harvested plants were separated into root, shoot and seed. The plant samples were first air-dried at room temperature and then in a drying chamber at 105 °C to constant weights. After drying, the samples were powered with IKA A11 mill for plant material.

For analysis of total Cd and Pb concentration in substrate, 2.0000 g of sample was weighted and digested with 20 mL of concentrated HNO$_3$ and slowly heated to boiling temperatures. The reaction mixture was heated until no brown vapors were generated. A mixture of 3 mL of concentrated H$_2$O$_2$ was added into the cooled reaction and the reaction mixture was heated slowly to boiling. After the termination of brown vapor generation, the reaction mixture was re-cooled and 3 mL of concentrated H$_2$O$_2$ was added. The reaction mixture was gradually heated to boiling and after no brown vapor was generated, the reaction mixture was cooled and quantitatively transferred to a volumetric flask of 100 mL [31]. A similar procedure was used for the plant samples digestion [32].

Preparation of the substrate samples for determination of the available forms of Pb and Cd was carried out by extraction with a DTPA (diethylenetriaminepentaacetic acid) buffer solution [33].

The concentration of cadmium and lead in the solution obtained by digestion were determined by the inductively coupled plasma-mass spectrometry, ICP-OES, Thermo ICAP 6300 duo [34].

2.3. Bioaccumulation Factor (BAF) and Translocation Factor (TF) Analysis

The bioaccumulation factor (BAF) was defined as the ratio of Cd or Pb concentration in the roots and those in the substrate used for plant growth [35], and it was defined using Equation (1). The BAF was calculated as:

$$BAF = \frac{C_{plant}}{C_{soil}},$$

where $C_{plant}$ and $C_{soil}$ represent Pb or Cd concentration in plants and substrate on dry weight basis, respectively.

The translocation factor is defined as the ratio of Cd or Pb concentration in the seed to those in the root [21], as given in Equation (2):

$$TF = \frac{C_{grain}}{C_{root}},$$

where $C_{grain}$ and $C_{root}$ represent Pb or Cd concentration in plants on dry weight basis.

2.4. Statistical Analysis

Data were processed using one-way ANOVA and Tukey’s HSD post hoc test to distinguish statistical differences between the transfer of Cd and Pb from water—to—plant, bioaccumulation factors of Cd and Pb during formation and maturation of seed and transfer coefficients of Cd and Pb during formation and maturation of seed. An independent sample t-test was performed to analyze
the bioaccumulation factor between Cd and Pb. In such a way, we analyzed the statistical difference between the two toxic metals. The level of statistical significance was set at 0.05. Statistical processing was performed using Microsoft Excel 2010 and SPSS Statistics 17.0. Two way ANOVA and Tukey’s post hoc test was also used to show interaction between treatments and PTEs.

3. Results

3.1. Transfer of PTEs from Water-to-Plant

Bioaccumulation and translocation of cadmium in quinoa during formation and maturation of seed within the 12 applied treatments is presented in Figure 1. Values in all parts of the plant for the treatments VII and IX and the difference between the content in the root and seed of the plant for the treatments IV, V, VI, VIII, X, XI and XII during formation of the seed were statistically significant (p < 0.05). At the stage of seed maturation, analysis showed a statistically significant difference (p < 0.05) between the root, stem and seed within treatments V, VII, VIII, IX, X, XI and XII.

![Figure 1](image-url)  
**Figure 1.** The transfer of Cadmium from water—to—plant, Legend: (a) Seed formation, F.I–F.XII—treatment of plants during formation of seed; (b) Seed maturation, M.I–M.XII—treatment of plants during maturation of seed. I—tap water; II—5 mg/kg of Pb; III—50 mg/kg Pb; IV—100 mg/kg Pb; V—5 mg/kg Cd; VI—50 mg/kg Cd; VII—100 pm Cd; VIII—5 mg/kg Pb and 5 mg/kg Cd; IX—50 mg/kg Pb and 50 mg/kg Cd; X—100 mg/kg Pb and 100 mg/kg Cd; XI—Pb max Cd min; XII—Pb min Cd max. Mean values within the same row with the different superscripts differ significantly (p < 0.05).

As for the seed maturation stage, the highest concentration of Pb was determined in the root for the treatment IV (21.82 mg/kg).
The highest value of BAF for Cd was within the treatment IV (1.27) and for Pb within the treatment X (0.35).

The transfer of Pb and Cd from water to the roots of the plant showed no statistically significant interaction between Pb and Cd (F = 1.733; p = 0.21). The transfer of Cd and Pb from water to the seed showed a statistically significant interaction between the two PTEs (F = 6.36; p = 0.028).

During maturation of the seed, analysis of the transfer of Cd and Pb from water to the roots of the plant showed no statistically significant interaction between Pb and Cd (F = 1.733; p = 0.21). The transfer of Cd and Pb from water to the seed showed a statistically significant interaction between the two PTEs (F = 12.19; p = 0.005). Further analysis confirmed that Cd and Pb were not significantly affecting treatments during formation and maturation of seed (p = 0.22; p = 0.49, respectively).

3.3. Bioaccumulation Factor

Bioaccumulation factor (BAF), for values of total content of Pb and Cd in substrate, during seed formation are presented in Table 2. These values indicate that the absorption was of medium intensity. The highest value of BAF for Cd was within the treatment IV (1.27) and for Pb within the treatment X (0.35).

The results show that statistical differences were observed for treatments II, VII, IX and X (p < 0.05). Medium intensity absorption was also observed, in the seed maturation stage (Table 3) with the highest value within the treatment XI for both Cd (0.78) and Pb (0.88). Results show statistical differences for treatments III, V, VI, VII, VIII and IX (p < 0.05).

DTPA extractable BAF of Cd and Pb (Figure 3) indicate that bioaccumulation was generally medium to high intensity. For the seed formation the highest value of Cd was for the treatment VII (5.27), while treatment IV showed the highest values for Pb (2.58). The highest value of Cd for the seed maturation was for the treatment VI (4.75), and for Pb for the treatment XI (5.51).
Table 2. Bioaccumulation factor of Cd and Pb, total content in substrate, the seed formation.

| Treatment | Cd          | Pb          |
|-----------|-------------|-------------|
| I         | 0.2051 ± 0.1179 a | 0.1240 ± 0.0131 a |

| XII       | 0.3671 ± 0.0804 a | 0.2317 ± 0.0313 a |

The statistical differences were expressed with different letters (a,b) (p < 0.05).

Figure 3. DTPA (diethylenetriaminepentaacetic acid) extractable bioaccumulation factors of (a) Cadmium and (b) Lead during formation and maturation of seed. The diversities were expressed as different letters (p < 0.05).

The seed forming stage has stronger absorption of Cd, except for the treatment VI (Figure 3). In contrast for Pb, the stronger absorption is generally observed in the seed maturation stage.

Translocation factor (TF) of cadmium and lead during formation and maturation of seed is presented in the Figure 4. There is no significant difference between values of TF in these two stages.
for lead. However, for cadmium statistically significant difference exists for treatments VIII, IX, X and XII. TF's values of metals in seed formation stage are lower than 1, except for control and treatment II for cadmium because of the low bioaccumulation in root for these two treatments.

**Figure 4.** Transfer coefficients of (a) Cadmium and (b) Lead during formation and maturation of seed. The diversities were expressed as different letters ($p < 0.05$). Where no letters are presented, there is no significant difference.

4. Discussion

The dominant toxic forms, accessible fractions, of the PTEs included in this study are free ions. It has been proved that their bioavailability is decreasing when the soil pH and organic content is increasing [36].

Distribution of Cd in the seed formation stage shows that the highest content was in the root of quinoa, with the highest concentration Cd within the treatments VII, 100 mg/kg Cd, (21.39 mg/kg), X, 100 mg/kg Pb and Cd, (19.76 mg/kg) and XII, 5 mg/kg Pb and 100 mg/kg Cd, (19.75 mg/kg). These results are consistent with the fact that in the treatments VII, X and XII, the highest concentration of Cd were applied (100 mg/kg in water for irrigation). The lowest Cd content was determined in the seed. In the seed maturation stage, the highest content can be observed in root and the lowest content in the seed. The highest concentration of Cd in the root was again within the treatments VII (35.45 mg/kg). Similar studies have shown low levels of metals in the seed, as well as a low translocation factor [22]. Studies of Holm Oak (Quercus ilex L.) exposed to the urban environment showed a significant concentration of Pb and Cd in leaves [37].

The maximum content of Pb, observing the overall distribution in quinoa during the seed formation and maturation, was determined in the root and the lowest was found in the seed. Within the seed formation stage, the highest concentration of Pb in the roots was determined for the treatments IV at 100 mg/kg Pb (Cd: 11.05 mg/kg), and X at 100 mg/kg Pb, (Cd: 11.79 mg/kg). The highest concentration in the seed was determined for the treatment X (0.57 mg/kg) with the highest concentration of Pb applied. Investigations of lead content in 30 varieties of Chinese cabbage (Brassica pekinensis L.), in the experiment, have confirmed that the amount of lead in the soil had a significant effect on the lead concentration in plants [38].

As for seed maturation stage, the highest concentration of Pb was determined in the root for the treatment IV (21.82 mg/kg). Result of this study are consistent with the study of wheat (Triticum aestivum) that were grown on the contaminated soil in the vicinity of the mine, which contain high concentrations of Pb (17.23 mg/kg) and Cd (42 mg/kg), showing high accumulation of these elements in the root of the plants [23]. Similar distributions of both Cd and Pb, were observed also in the wheat with the highest content in the root [30].

According to some authors, the bioaccumulation factor is a compelling indicator of metal accumulation capacity [39]. Transfer of PTEs from soil into the plants is considered to be one of the main indicators of human exposure to contamination [24,40].
Plants’ ability to uptake and accumulate metals can vary greatly among different species or even within cultivars of the same species. An example of such a study is the research of 32 hybrid rice varieties grown on the contaminated soil. Results of this study indicated that there were significant differences in the accumulation and tolerance for lead and cadmium between all tested hybrids [27]. Also, 14 sunflower hybrids have shown significant differences in the accumulation of Cd and Zn [28]. The study of concentration levels of Cr, Cd and As in a soil-wheat system showed that bioaccumulation of Cd was much higher than other elements [41]. The experiment of the accumulation Pb by mandarin orange trees, irrigated with water containing different concentrations of Pb, showed that accumulation remained highest in plants that received the highest concentration of Pb via irrigation [42]. Investigation of bioaccumulation of PTEs by sorghum and sunflower on contaminated agricultural soil showed that the highest concentration of investigated elements (Cd, Cr, Cu, Ni, Pb) was in roots, while BF roots was the lowest [43].

Different plant species may accumulate lead with the highest concentration in the root [44] and, for this reason, an important step towards the control of health risks is obtaining an understanding of Pb accumulation mechanism, as well as its translocation to the aerial parts of plant.

TF’s values of metals in seed formation stage are lower than 1, except for control and treatment II, 5 mg/kg Pb, for cadmium because of the low bioaccumulation in root for these two treatments. These values, TF < 1, indicate a low level of translocation from the roots to the seed. Also, TF’s values of metals in seed maturation stage are lower than 1, showing a deficient transport of metals, from the root to the seed, especially for lead. In this way, the edible parts of the plant are protected from potentially toxic elements contamination. These results indicate that quinoa only uptakes, but does not accumulate cadmium and lead, while the root is a barrier that prevents further translocation of metals to seed. Also, low metal accumulation indicates lower risk for primary consumers [45]. The high values of Cd and Pb in the root of pea plant with very low translocation to the edible parts of the plant were reported [45]. Similar studies of metal accumulation and translocation by miscanthus also reported limited translocation to aerial parts of plant [25,26]. Our results are not consistent with the study [39] that reported high TF values for Cd in wheat. The higher TF were found for Cd and Pb in *Plantago major* L. [21]. The highest concentration of Pb in beans was determined in shoot with very limited translocation to edible parts of the plant [46].

Metal excluders are defined as crops that can accumulate metals in small quantities in the edible parts, so their products are safe for consumption even when they are grown on the moderately contaminated soils [47]. This concept is based on the fact that several studies confirmed a significant difference in accumulation and distribution of metals between different varieties of the same culture. On the other hand, the plants that are suitable for phytostabilization accumulate trace elements in the roots and translocation of these elements are limited, which prevents their transfer into the food chain [48].

### 5. Conclusions

The highest concentrations of metals were determined in the roots, for both studied growth stages of quinoa. BAF of Cd and Pb indicate that bioaccumulation was generally medium to high intensity. In addition, TF values were lower than 1, showing very limited translocation from root to seed and making quinoa suitable for Cd and Pb phytostabilization.

The results of our study indicated that quinoa adopts potentially toxic metals from substrate with scarce translocation to the plant parts, in particular to the seed. This conclusion paves the way for quinoa as a potential lead and cadmium excluder.

The limitation of this study is that they speciation/fractionation of Cd and Pb was not fully determined. Future research should analyzes the safety of quinoa grown in contaminated environments for human consumption. Also, it is suggested to compare the bioaccumulation efficacy of other PTEs from water to quinoa under irrigation with wastewater.
Author Contributions: The manuscript was read, discussed, and approved by all authors. B.Z. and V.R. designed and performed the experiments; I.D. and V.R. analyzed the data and contributed to the writing of the paper. All authors have read and agreed to the published version of the manuscript.
