Abstract: There is a huge need to search for new treatment options and potential biomarkers of therapeutic response to antidepressant treatment. Depression and metabolic syndrome often coexist while a pathophysiological overlap, including microbiota changes, may play a role. The aim of the study is to assess the effect of probiotic supplementation on symptoms of depression, anxiety and stress, metabolic parameters, inflammatory and oxidative stress markers, as well as faecal microbiota in adult patients with depressive disorders depending on the co-occurrence of MetS. The trial will be a four-arm, parallel-group, prospective, randomized, double-blind, controlled design that will include 200 participants and will last 20 weeks (ClinicalTrials.gov identifier: NCT04756544). The probiotic preparation will contain Lactobacillus helveticus Rosell®-52, Bifidobacterium longum Rosell®-175. We will assess the level of depression, anxiety and stress, quality of life, blood pressure, body mass index and waist circumference, white blood cells count, serum levels of C-reactive protein, HDL cholesterol, triglycerides, fasting glucose, faecal microbiota composition and the level of some faecal microbiota metabolites, as well as serum inflammatory markers and oxidative stress parameters. The trial may establish a safe and easy-to-use adjunctive treatment option in a subpopulation of depressive patients only partially responsive to pharmacologic therapy.

Keywords: depression; metabolic syndrome; probiotics; microbiota; inflammation; oxidative stress

1. Introduction

Metabolic syndrome (MetS) and depression are among the most common and debilitating disorders worldwide [1]. Moreover, depressive disorders (DDs) often coexist with MetS, thus further increasing mortality risk [2,3]. A meta-analysis [4] showed that individuals with depression had 1.5 times higher odds of developing MetS which is diagnosed in 30% of depressed subjects [5]. Although the exact mechanisms underlying
this association are poorly known, the high co-occurrence rate of DDs and MetS suggests a possible pathophysiological overlap. Among others, altered microbiota has been suggested as one of the factors [1,3,5–9]. The term microbiota refers to trillions of organisms present in the human body. They have a substantial impact on health, including the human immune status [10,11]. The diversity and stability of the microbiota are important indicators of the overall health condition of an individual [12]. The intestinal microbiota has been shown to be an essential part of the bidirectional and complex gut-brain axis [13,14]. The diversity of the gut microbiota has emerged to play a significant role in the occurrence of mood and anxiety disorders [12,15–20]. Moreover, there is scientific data on the implication of the intestinal microbiota function in the etiopathogenesis of MetS and the connection of dysbiosis with abdominal obesity [21,22]. The complex net involving depression, metabolic diseases, inflammation and oxidative stress (OxS) parameters has been recently discussed in another paper [23].

Certain microbiota interventions, e.g. introduction of the Mediterranean-style diet, intake of fermented food, dietary fibre, plant-based diet and consumption of prebiotics (oligosaccharides, fructans) may reduce the risk of developing depression [24]. Furthermore, recent trial reports on using probiotics (live microorganisms which, if consumed in adequate amounts, bring the host health benefits [25]) demonstrated their usefulness in depression or anxiety outcome measures [26–30]. It has been suggested that the microorganisms can form a new group of drugs named “psychobiotics” [31], which makes future research in the area very promising. Moreover, the main findings of the recent reviews are that some of the selected probiotics can discretely improve some of the clinical components of the MetS, as well as some inflammatory biomarkers associated with the syndrome [32–34]. However, holistic dietary changes may be necessary as an adjunct to prebiotics or probiotics treatment to provide long-term improvements.

The primary aim of the study is to assess the effect of probiotic supplementation on diminishing symptoms of depression in adult patients diagnosed with depressive disorders depending on the co-occurrence of MetS. The secondary aims are to assess the effect of probiotic supplementation on anxiety and stress symptoms, metabolic parameters, inflammation and oxidative stress markers, SCFAs level and microbiota composition in faeces in these patients. The preliminary aim is to compare the markers of faecal microbiota function and composition, as well as inflammation and OxS parameters between depressed patients with and without MetS.

The study hypothesis is that comorbidity of depression and MetS increases the probability of therapeutic effect of probiotic supplementation in the case of depressive and anxiety symptoms via the increase of α-diversity in faecal microbiota, and thus the synthesis of SCFAs. If it is true, this may help to establish a subpopulation of patients vulnerable to positive response to probiotic supplementation. Additionally, along with the evaluation of inflammatory and oxidative status parameters, this could determine potential biomarkers of therapeutic response among depressive patients.

2. Materials and methods

2.1. Design
The trial will be a four-arm, parallel-group, prospective, randomized, double-blind, controlled design that will last 20 weeks (eight weeks for an intervention period). The trial was registered in the clinicaltrials.gov registry (ClinicalTrials.gov identifier: NCT04756544). 

**PRO-DEMET study protocol design and publication have been planned according to CONSORT 2010 checklist.**

### 2.2. Patients

The study population will consist of 200 patients recruited in the Central Teaching Hospital (psychiatric inpatient and outpatient clinics) of the Medical University of Lodz, Poland, other psychiatric outpatients clinics in Lodz and through advertisements in social media. All the subjects will be diagnosed with depressive disorders according to the upcoming International Classification of Diseases (ICD-11) [35], and half of them with accompanying MetS diagnosed according to International Diabetes Federation (IDF) criteria [36].

As for the sample size, our approach is as follows. An online tool (https://www.gigacalculator.com/calculators/power-sample-size-calculator.php) estimated that an overall group of 195 individuals (39 per group) is required to detect possible intergroup differences. After a preliminary ANOVA analysis, we will conduct post hoc tests to ascertain the exact differences.

Ideally, for post hoc analyses the population should be bigger than 65 people per group for MADRS score comparisons, 74 per group for SCFAs level comparisons and 84 per group for alpha diversity comparisons, however, with 40 persons per group it still seems possible to detect a statistical difference between groups regarding all the above outcomes. The details of sample size calculations are described in Appendix A section.

**Randomisation**

The patients will undergo randomization stratified according to MetS presence and will be allocated to probiotic or placebo treatment in ratio 1:1 by an independent researcher. The trial participants, care providers, outcome assessors and data analysts will be blinded after assignment to interventions. Unblinding will be permissible only if any serious adverse events occur during the course of the trial. Randomization will be computed using a computer random number generator (https://www.randomizer.org/).

The study groups will be as follows:

1. PRO-DMS: depression + MetS + probiotic
2. PLC-DMS: depression + MetS + placebo
3. PRO-D: depression + probiotic
4. PLC-D: depression + placebo

Each patient will receive information on the purpose and structure of the investigation. Deliberate written and informed consent to take part in the study will be required. Anyone who fails to meet the inclusion criteria will not qualify for participation in the project. The participants will be able to opt out of the study at any time before or during the protocol. The data collected and samples will be pseudoanonymised for the purposes of future use and the informed consent form will include information on the future use of samples, material and personal data. The study will be conducted in accordance with the
Declaration of Helsinki, and the principal study investigator (PSI) applied to the Bioethics Committee of the Medical University of Lodz for an approval of the whole protocol.

The study timeline will consist of the following appointments (Fig. 1):

- **V0**, “recruitment visit”, preferably an online formula: assessment of the inclusion and exclusion criteria, the study questionnaire (SQ) and the MADRS completion, informed consent, full psychiatric examination;
- **V1** (no longer that five days after V0), “randomisation visit”: DASS, WHOQOL-BREF completion, BP, BMI, WC measurements, blood and stool collection;
- **t1-t3**: personal, telephone or e-mail monitoring every two weeks according to the monitoring questionnaire (MQ);
- **V2**, “the end of the study visit”, eight weeks after V1: MQ, MADRS, DASS, WHOQOL-BREF completion, BP, BMI, WC measurements, blood and stool collection;
- **V3**, “a follow-up visit”, after 12 weeks after V2: SQ, MADRS, DASS, WHOQOL-BREF completion, BP, BMI, WC measurements, stool collection.

**Figure 1.** The schedule of enrolment, interventions, and assessments.

Abbreviations: BMI: body mass index; BP: blood pressure; CBC: complete blood count; CRP: C-reactive protein; DASS: Depression, Anxiety, Stress Scale; fGlc: fasting glucose; HDL-c: high-density protein cholesterol; MADRS: Montgomery-Asberg Depression Rating Scale; MC: microbiota composition; SCFAs: short-chain fatty acids; SQ: study questionnaire; TG: triglycerides; WC: waist circumference; WHOQOL-BREF: The World Health Organisation quality of life-BREF.
To be qualified for the trial, the subjects have to meet all the inclusion criteria and none of the exclusion criteria, as stated in Tab. 1.

Table 1.
Eligibility criteria

Inclusion criteria:
1. Depressive disorders diagnosed according to ICD
2. Age between 18 and 70 years
3. MADRS score $\geq 13$
4. Antidepressant and antianxiety medications or psychotherapy not changed three weeks prior to the beginning of the study
5. DMS study groups: MetS diagnosed according to the International Diabetes Federation (IDF)

**Exclusion criteria:**

1. Pregnancy;
2. An infection and/or treatment with antibiotics in the previous four weeks;
3. Supplementation with probiotics or prebiotics in the previous four weeks;
4. Having a diagnosis of autoimmune, serious immunocompromised, inflammatory bowel diseases, cancer, IgE-dependent allergy, severe kidney failure or unstable thyroid dysfunction in the previous four weeks;
5. Psychiatric comorbidities (except for a specific personality disorder, an additional specific anxiety disorder and caffeine or nicotine addiction);
6. Regular treatment (more than three days a week) with proton-pump inhibitors (PPIs), metformin, laxatives, systemic steroids or nonsteroidal anti-inflammatory drugs (NSAIDs) in the previous four weeks;
7. Following a specific diet or a significant change in a dietary pattern in the previous four weeks;
8. A significant change in daily physical activity or an extreme sport activity in the previous four weeks;
9. A significant change in dietary supplementation in the previous four weeks;
10. A significant change in a smoking pattern in the previous four weeks;
11. A major neurological disorder or any medical disability that may interfere with a subject’s ability to complete study procedures;
12. High risk of suicide according to the Tool of Assessment of Suicide Risk (TASR);
13. Current or recent participation in another research study involving an intervention which may alter outcomes that are relevant for this study;
14. Any other condition or situation which, in the investigators’ opinion, would affect the compliance or safety of the individual involved;
15. D study groups: MetS diagnosed according to the International Diabetes Federation (IDF).

**Reasons for discontinuation of the study by a participant:**

1. Withdrawal of the informed consent;
2. An infection and/or treatment with antibiotics during the course of the trial;
3. Consuming any probiotics other than those studied during the course of the trial;
4. Lack of compliance with the probiotic supplementation;
5. Any change in the drug regimen during the study;
6. Any exclusion criteria identified after the enrolment;
7. Any serious adverse event occurring during the course of the trial.

### 2.3. Intervention

At the beginning of the study (V0), the participants will be requested to follow their routine physical activity, dietary intakes or any other lifestyle activities throughout the whole trial. These evaluations will be performed by means of the study-specific self-assessment Monitoring Questionnaire (MQ). The probiotic groups (PRO-DMS and PRO-D) will receive one capsule containing the probiotic mixture powder in the amount of $3 \times 10^9$ colony forming units.
units (CFU). The probiotic preparation will contain two bacteria strains, i.e., Lactobacillus helveticus Rosell®-52, Bifidobacterium longum Rosell®-175 and excipients, i.e., potato starch, magnesium stearate, and the capsule shell of hydroxypropyl methylcellulose. The placebo groups (PLC-DMS and PLC-D) will receive the same capsule containing only the excipients, i.e., maize starch, maltodextrins, and the capsule shell. The placebo will be indistinguishable in colour, smell, and taste from the probiotic formulation. The participants will be given the supplements before breakfast.

2.4. Outcome measures

The primary outcome measure will be the Montgomery–Asberg Depression Rating Scale (MADRS). The secondary outcomes measures will include the Depression, Anxiety and Stress Scale (DASS) with subscales scores, quality of life level assessed with the WHOQoL-BREF instrument, blood pressure (BP), body mass index (BMI) and waist circumference (WC) measures, white blood cells count (WBC) with differential and leucocytes ratio (LR), serum levels of C-reactive protein (CRP), HDL cholesterol, triglycerides (TG), fasting glucose (fGlc), faecal microbiota α-diversity and the level of faecal SCFAs. The tertiary outcome measure will be the level of inflammation markers (IL-6 and TNFα) and oxidative stress parameters (TAC and MDA) in the blood serum (future use of biological material) (Fig. 1).

2.4.1. Questionnaires and scales

SQ has been constructed to collect basic information concerning sociodemographic and health-related data. The participants will provide information on personally identifying information, diet, smoking cigarettes, physical activity, as well as their health status, the use of dietary supplements and medications. As the collected or processed data will belong to the special category, personal data will be pseudoanonymised.

As gut microbiota function is associated with self-reported long-term dietary patterns, the protocol includes diet assessment of based on the Food Frequency Questionnaire (FFQ). We will use Polish self-administered FFQ-6 developed by Wądołowska [37]. FFQ will assess consumption of different food groups. The participants will be asked to estimate their “usual consumption” over the past year. The investigator administering the FFQ will invite the participants to describe their “usual” diet, rather than focus on their latest dietary consumption. Cross-check questions will be used to correct misreporting of fruit and vegetables as these tend to be overreported. Based on FFQ, the Healthy-Eating Index (HEI), which has been validated for studying the microbiome [38], will be calculated for each study participant.

The Montgomery–Åsberg Depression Rating Scale (MADRS) [39] was developed to assess depressive symptom severity in the investigation of treatment response. It consists of ten items chosen based on their ability to detect depression change, demonstrates psychometric properties equal to other standardized measures of depression and is one of the most extensively used clinician-rated scales of depressive severity in clinical research [40]. We decided on the cut-off value of 13 points based on the clinical utility study by Duarte [41].
The Depression Anxiety Stress Scales (DASS) is a set of three self-report scales designed to measure the negative emotional states of depression, anxiety and stress [42]. Each of the three DASS scales contains 14 items, divided into subscales of 2-5 items with similar content. Subjects are asked to use 4-point severity/frequency scales to rate the extent to which they have experienced each state over the past week.

WHO Quality of Life-BREF (WHOQOL-BREF) instrument [43] will be used to measure quality of life. It is a person-centred, multilingual, easily administered tool for subjective assessment and it is designed for use in a wide range of diseases and conditions in both clinical settings and clinical trials.

The Tool for Assessment of Suicide Risk (TASR) [44] was designed to be used by clinicians to document their assessment of a patient who may be suicidal. TASR may be used to ensure that the most pertinent individual, symptom and interview details necessary for the assessment of suicide risk have been addressed by the clinician and may be a ‘bedside’ tool that helps the clinician determine the risk for suicide. We will use TASR to exclude severe suicide risk.

Although we apply several questionnaires that are self-administered, the study protocol includes an option for responses to be reviewed and any queries clarified in a face-to-face, e-mail or telephone interview. To ensure that an FFQ is acceptable and understood by the subjects of the study it will be explained first. Clear instructions will be given at the beginning of the questionnaire and supported by relevant examples to resolve any doubts. Missing data on self-reported questionnaires will be treated in two ways. Questionnaires with more than 25% of incomplete questions will be excluded. In the case of questionnaires not exceeding the limit for incomplete data, an average value for the population will be substituted.

2.4.2. Biological samples

Venous blood will be collected by qualified nurses according to the reliable protocols of collection, transport, and storage of biological material. Twenty milliliters (5 mL) of whole arm vein blood will be collected from each person in all the groups. Samples of fasting blood will be collected, from the subjects after overnight rest, in the morning, between 8:00 and 10:00 a.m. Complete blood count (CBC), C-reactive protein (CRP), HDL-c, TG and Glc will be measured subsequently. To obtain serum for future analysis (TAC, MDA, Il-6, TNF-α), blood will be transferred to the sterile tubes without an anticoagulant (on the so-called clot) and left at room temperature (approximately 30-45 minutes) to form a clot. After centrifugation at 1000xg (2400 rpm) for 10 minutes, the serum (supernatant) will be carefully separated from the clot into Eppendorf tubes. Approximately 2 mL of serum should be obtained from each patient in each time point. Until further analysis is made, the blood samples will be preserved in pyrogen/endotoxin free collecting Eppendorf tubes (in 250-500μl aliquots to avoid repeated freeze-thaw cycles) and stored frozen at –80°C.

Samples of biological material, i.e., faeces, will be taken by the patients themselves. Every patient entering the survey will be asked to collect a stool sample twice. The study participants will be advised not to use laxatives, eat synthetic fat substitutes, or take fat-blocking nutritional supplements. It will be recommended to wait 48 hours after potential barium enema introduction. The patients will be sampling faeces after overnight fasting, to
establish a common reference point for food intake, a factor determining SCFAs synthesis. Following collection, the participants will be asked to deliver the sample as soon as possible to the study investigators. After delivery, the samples will be stored at −80°C in the BioBank of the Medical University of Lodz until the analyses are performed.

**SCFAs**

The following SCFAs will be evaluated: acetic acid (C 2:0), propionic acid (C 3:0), isobutyric acid (C 4:0 i), butyric acid (C 4:0 n), isovaleric acid (C 5:0 i), valeric acid (C 5:0 n), isocaproic acid (C 6:0 i), caproic acid (C 6:0 n), and heptanoic acid (C 7:0). SCFAs will be isolated from faeces according to the Zhao method (modified by Roediger). Approximately 0.5 g of faeces will be diluted in 5 ml of sterile water and homogenized for five minutes using the hand homogenizer. The pH will be adjusted to pH 2-3 using the 5M HCl. The samples will be vortexed for ten minutes and centrifuged at 5000 rpm for 20 minutes. The clear supernatant (after filtration using the Ø 400 µm filter) will be transferred to a chromatographic vial and will be analysed with gas chromatography (GC) using the Agilent Technologies 1260 A GC system with a flame ionization detector (FID) and a fused-silica capillary column with a free fatty acid phase (DB-FFAP, 30 m0.53 mm0.5 um). SCFAs will be qualitatively identified by comparing the retention times to the standard, i.e. 2-ethylbuthyric acid. For the quantitative analysis, ChemStation Software (Agilent Technologies, UK) will be used. The measurement will be performed at the Department of Human Nutrition and Metabolomics, Pomeranian Medical University, Szczecin.

**Microbiota composition**

To characterize the microbial composition in the patients and identify changes over the course of the trial, we will perform the sequencing of the hypervariable region (V3 and V4 regions) of the 16S ribosomal RNA (rRNA) gene and fungal ITS1 (internal transcribed spacer) region. The procedure will be divided into four stages: 1. DNA isolation, quality and quantity assessment; 2. DNA 16S (V3-V4) library preparation with library validation; 3. next generation sequencing (NGS) on the Illumina platform of 16S V3-4 rRNA, paired-end 2x250bp with .fastq files generation; 4. bioinformatic analysis and report preparation. The bacterial and fungal DNA will be extracted from faecal samples with the use of the dedicated kit, followed by the DNA quality and quantity assessment. To assess the diversity of the microbiota in each patient, the bacterial and fungal DNA of the 16S ribosomal RNA (rRNA) gene will be amplified using the set of universal primers targeting the hyper-variable V3-V4 regions (for the bacterial composition analysis) and ITS1 region (for the fungal composition analysis). After the PCR reaction, the quality and quantity of the amplified product will be assessed, then the sequencing libraries will be prepared. After amplification of the libraries (for each patient and in each time point) the libraries will be sequenced on the Illumina platform (paired-end 2x250bp with .fastq files generation). Finally the reads - the 16S rRNA gene sequences / ITS1 region will be clustered into Operational Taxonomic Units (OTUs) at a similarity cut-off value of 97%. Microbiota gene sequencing will be performed by Bionanopark, Lodz.

Output reads will be analysed using the Qiime2 platform. For each sample dataset, the same quality check and filtration criteria will be applied. The read quality will be checked using FastQC software and statistics will be performed in Qiime2. The amplicon errors, chimeric
sequences will be corrected by denoising using the q2:dada2 package. Following, the sequences will be clustered into Operational Taxonomic Units (OTU) based on sequence similarity within the reads. The OTU sequences will be aligned based on GreenGenes database. OTU table will be constructed representing the abundance of each OTU in each microbial sample. An alpha diversity analysis will be performed by measuring following indexes: Shannon, Simpson, Chao1, ACE. It will be presented as a box-and-whisker plot for each index. A beta diversity analysis will be performed on the samples grouped by their origin. Weighted Unifrac and principal coordinate analysis (PCoA) will be measured to display microbiome distances between the samples. The results of the bacterial taxonomic analyses will be presented at the genus level as a heatmap. Additionally, multivariate ANOVA with permutations (PERMANOVA) will be used to test differences between the groups.

**Inflammation and oxidative stress parameters**

The serum obtained from the patients representing all the groups (PRO-DMS; PLC-DMS; PRO-D and PLC-D) will be used to assess the inflammation protein level and oxidative stress parameters using the Enzyme-linked Immunosorbent Assays (ELISA) with the use of the highly specific antibodies. Small aliquots of serum (100 or 200 μl per patient) will be used in each ELISA assays. The intensity of the final colorimetric reaction, in proportion to the amount of protein/substrate bound, will be measured using the plate reader (ELx800, BioTek, USA) at 450 nm. The obtained results will be compared to the standard solution of known concentrations (specific for individual ELISA kits).

Based on ELISA, the following inflammation and OxS parameters will be analyzed:

1. The Interleukin-6 (IL-6) is a multi-functional cytokine that regulates immune responses, acute phase reactions and hematopoiesis and may play a central role in host defense mechanisms [45]. It acts on a wide range of tissues, exerting growth-induction, growth-inhibition, and differentiation respectively, depending on the nature of the target cells [46–48]. We plan to use the Human IL-6 ELISA Kit (Diaclone, 950.030.192, minimum detectable dose of 2pg/ml) or Interleukin-6 Human ELISA Kit (Biovendor, RD194015200R). A highly specific capture antibody against IL-6 is coated to the wells of the microtiter strip plate provided in the kit.

2. Tumor Necrosis Factor alpha (TNFα) is a polypeptide cytokine produced by monocytes and macrophages. It functions as a multipotent modulator of immune response and further acts as a potent pyrogen. TNFα circulates throughout the body responding to stimuli (infectious agents or tissue injury), activating neutrophils, altering the properties of vascular endothelial cells, regulating metabolic activities of other tissues, as well as exhibiting tumoricidal activity by inducing localized blood clotting [46–48]. We plan to use the Human TNF alpha ELISA Kit (Diaclone, 950.090.192, minimum detectable dose of 8pg/ml) or TNF-alpha Human ELISA, High Sensitivity Kit.
3. MDA (Malondialdehyde) is a naturally occurring product resulting from lipid peroxidation of polyunsaturated fatty acids. It is also produced in the prominent product in thromboxane A2 biosynthesis wherein cyclooxygenase 1 or cyclooxygenase 2 metabolizes arachidonic acid to prostaglandin H2. MDA has the mutagenic and carcinogenic effect [49]. We plan to use the High Sensitive ELISA Kit for Malondialdehyde (Cloud Clone Corp. HEA597Ge, minimum detectable dose of 4.94 ng/ml). A highly specific capture antibody against MDA is coated to the wells of the microtiter strip plate provided in the kit.

4. Total antioxidant capacity (TAC) (Total antioxidative status - TAS) is an analyte frequently used to assess the antioxidant status of biological samples and can evaluate the antioxidant response against the free radicals produced in the body in a given disease or analyzed condition. Overproductions of ROS or insufficient defense mechanisms lead to a dangerous disbalance in the organism observed in lipid peroxidation, mutagenic effect on DNA. The elevated level of ROS is associated with pathomechanisms implicated in aging and over 100 human diseases, e. g. cardiovascular disease, cancer, diabetes mellitus, inflammatory disease [50,51]. TAC measurements provide a tool for establishing links between antioxidant capacity and the risk of disease as well as for monitoring of antioxidant therapy. We plan to use the ImAnOx (TAS) Antioxidative Capacity Kit (Immunodiagnostik, KC5200, minimum detectable dose of 130 μmol/l).

The estimated reference values of TAC (Based on Immunodiagnostik studies of EDTA-plasma and serum of apparently healthy persons, n = 69):

- low antioxidative capacity < 280 μmol/l
- middle antioxidative capacity 280-320 μmol/l
- high antioxidative capacity > 320 μmol/l.

Detection of the IL-6 and TNFα in the serum

A highly specific capture antibodies against IL-6 or TNFα are coated to the wells of the microtiter strip plate provided in the kits. The sample (serum) is added to the wells in the plate. Binding of IL-6 or TNFα in the samples and known standards to the biotinylated antibodies is followed by subsequent binding of the secondary antibody (Streptavidin with Horseradish Peroxidase). Any excess unbound analyte and secondary antibody are removed. Next, the HRP conjugate solution is added, after incubation excess conjugate is removed. A chromogen substrate - TMB (3,3′,5,5′-Tetramethylbenzidine) is added to the wells resulting in a progressive development of a blue coloured complex with the conjugate. The colour development is then blocked by addition of acid turning the resultant final product yellow. The intensity of the produced coloured complex is directly proportional to the concentration of IL-6 or TNFα present in the samples and standards.
Detection of MDA in the serum

The monoclonal antibody specific to malondialdehyde is pre-coated onto a microplate. A competitive inhibition reaction is launched between biotin labeled malondialdehyde and unlabeled malondialdehyde (standards or samples) with the pre-coated antibody specific to MAC. After incubation, the unbound conjugate is washed off. Next, avidin conjugated to Horseradish Peroxidase (HRP) is added to each microplate well and incubated. The amount of bound HRP conjugate is reverse proportional to the concentration of malondialdehyde in the sample.

Determination of TAC in the serum

The antioxidative capacity is determined by the reaction of antioxidants present in the sample with a defined amount of exogenously provided hydrogen peroxide (H$_2$O$_2$). During the incubation H$_2$O$_2$ generates reaction products which absorb at 450 nm. Due to this effect and self-absorption, each sample has to be measured in two different conditions (with and without addition of enzyme). The antioxidants in the sample eliminate a certain amount of the provided hydrogen peroxide. The residual H$_2$O$_2$ is determined photometrically by an enzymatic reaction which involves the conversion of TMB to a colored product. After addition of a stop solution, the samples are measured at 450 nm in a microtiter plate reader. The difference in the values of the samples (those with and without the enzyme) is inversely proportional to the antioxidative capacity.

Characteristics of the ELISA assays used to assess the inflammation and OxS parameters are described in Appendix B.

2.5. Data Management

The study will use both self-administered and specialist-administered questionnaires filled in as face-to-face, paper-and-pencil or on-line administration. The subjects will have an opportunity to review responses and clarify queries in a face-to-face, online meeting, by e-mail or a telephone interview. To make sure that questionnaires are acceptable and understood by the subjects of the study they will be explained first with clear instructions and relevant examples given.

Collected samples will include blood samples collected by qualified nurses, whereas faeces samples will be collected by the study participants themselves. Data entry will be validated by the principal study investigator and data review will be performed by the co-investigators. The data will be organised as follows: 1. dataset: questionnaires filled in in the Microsoft Word (.docx) format directly converted to PDF format; 2. dataset: description of full psychiatric examination. 3. dataset: laboratory findings (HDL-ch, TG, fGlc, AST, ALT, CBC, CRP, TAC, MDA, TNF-alpha, Il-6 in blood, MC digital results with bioinformatics analysis results in a graphic form, SCFAs concentration in faeces) provided by laboratories in PDF format files. All the data will be summarized in the Microsoft Excel format. The files will be named according to pseudoanonimisation of the study participants. We plan to reuse the data in future research.

The data will be catalogued in a standardized way in compliance with the requirements of FAIR standards. The data will be physically stored in the office of PSI in paper and electronic form. PSI will use automatic backup services online ensuring protection against viruses by using anti-virus software, encrypted and protected by passwords so that access to
the data will be restricted. Selected data will be facilitated by open research data repository Zenodo without disclosure of the personal data. The metadata will be based on a generalised metadata schema used in Zenodo which includes the title, creator (including ORCID number), date, contributor, subject, description, format, resource type, DOI, access rights. A metadata description will be stored in JSON-LD format.

According to the General Data Protection Regulation (EU) 2016/679 (GDPR), a study participant will provide informed consent to data processing for one or more purposes. To protect all the patients, the only way to identify an individual patient’s data will be by looking for his/her specific ID code printed in the informed consent.

CC-BY-NC-ND 4.0 type of creative common license schema will be applied.

2.6. Ethics

Each patient will receive information on the purpose and structure of the investigation. Deliberate written and informed consent to take part in the study will be required. The data collected and samples will be pseudoanonymised for the purposes of future use and the informed consent form will include information on the future use of samples, material and personal data. The study will be conducted in accordance with the Declaration of Helsinki.

The study protocol has been approved by the Bioethics Committee of the Medical University in Lodz, Poland (reference number RNN/228/20/KE) on the 15th of December 2020.

2.7. Analyses

As regards microbiota composition, we will assess α-diversity (within-sample diversity; richness using the observed OTUs), β-diversity (diversity of microbial community structure) and taxa abundance.

To verify the hypothesis that persons with depression and accompanying MetS are more prone (than those without MeS) to microbiota dearrangement post probiotic ingestion, the repeated measures ANOVA and modelling the relationship between a multivariate data and predictor variables will be used. Similar approach will be used to investigate hypothesized change in MADRS score, SCFA and metabolic parameters before and after probiotic intervention.

Differences regarding variables i.e., clinical symptom severity (according to MADRS and DASS scores), α-diversity indexes, β-diversity between the groups will be tested using t-test or ANOVA. Correlations between symptom severity and relative abundances of phyla, genera, and species as well as metabolic, inflammation and OxS parameters will be assessed using a correlation test. The level of significance for statistical tests will be 5%. All statistical analyses will be performed using Statistica.

As for the inflammation and oxidative stress analysis, an ANOVA Kruskal-Wallis test or Mann-Whitney test (depending on the number of groups), and Neuman-Keuls’ multiple comparison test will be used to compare the levels of protein /substrate immunoexpression (assessed in ELISA assays), SCFAs levels, microbiota and MADRS score between the groups of the patients. Spearman’s rank correlation coefficient, Mann-Whitney test and ANOVA Kruskal-Wallis tests will be performed in order to evaluate the relationship
between the protein immunoexpression levels, SCFAs and the patients’ metabolic parameters.

3. Discussion

Obviously, our study protocol has both strengths and limitations. First of all, taking study population criteria into account, we decided to incorporate the whole category of depressive disorders according to the upcoming ICD-11 as the first step of eligibility screen in our study. The new diagnosis in this classification, underlying its impact on patients’ everyday functioning and quality of life, is anxious depression [35]. Additionally, the ICD-11 includes the category of mixed depressive and anxiety disorder (MDAD) in this section because of its importance in primary care settings and because of evidence confirming its overlap with mood symptomatology [52]. Therefore, our inclusion criteria may provide the basis for performing a study of the real-life population disabled because of depressive symptoms. On the other hand, the population will not be as homogenous as it would be with patients with MDD included only. Furthermore, MetS, as a set of anthropometric, clinical and metabolic abnormalities (obesity, insulin resistance, dyslipidaemia and hypertension), has had different definitions developed and some of the cut-offs of its criteria vary. In our research we decided to use the International Diabetes Federation (IDF) definition and criteria because they address both clinical and research needs, providing a tool suitable for worldwide use [36].

Our microbiome may be modulated by numerous circumstances, especially diet [53]. Consumption of complex carbohydrates rich in dietary fibers, both the quantity and type of fat, as well as the type and amount of proteins in the diet modulate the Firmicutes/Bacteroides ratio in the gut having substantial effects on the gut microbiota [54]. Another strength of our study is to use self-reported and validated for polish conditions FFQ to assess dietary factor and then use it in statistical analysis. Apart from diet, there are many other factors influencing our microbiome such as the mode of delivery (vaginal or caesarean), the mode of feeding in the early infancy (breastfeeding vs. formula), exposure to viral or bacterial antigens, treatment with antibiotics and several other groups of pharmacotherapeutics, genetic predispositions, age, environmental factors such as air pollution, exercise or stress [55–60]. The factors that may influence the microbiota changes in the course of our study are included in our original questionnaires: SQ at the beginning of the protocol and in the follow-up visit and MQ in the monitoring process including V2 visit. Unfortunately, for obvious reasons we are not able to control most of environmental factors influencing the microbiota of the study subjects such as air pollution, stressful life events, or genetics.

It is well-known that the probiotic effects are strongly strain-dependent. We will supplement the probiotic mixture of bacterial strains Lactobacillus helveticus Rosell®-52 and Bifidobacterium longum Rosell®-175. The above strains have been studied in experimental and animal models [61–65] as well as a few clinical studies assessing the functioning of microbiota-gut-brain axis both in healthy subjects and depressed patients [66–69]. Moreover, in an animal model of MetS elevations in tumour necrosis factor α (TNF-α), interleukin (IL)-1β, IL-6, and IL-10, as well as expression of IL-6 mRNA, were attenuated in L. helveticus treated rats [70].
Additionally, recent evidence suggests that intestinal Bifidobacterium species (spp.) positively correlates with improved insulin resistance and obesity, and this might be linked to metabolic inflammation [71].

It should be emphasized that different individuals can have taxonomically different but functionally similar microbiota [72], which makes functional assessment of microbiome health important. SCFAs are the most representative metabolites of fibre anaerobic fermentation [73] and also have the ability to diffuse across the blood-brain barrier [74]. There is evidence that SCFA receptor, namely FFAR3, is expressed in the brain tissue and sympathetic ganglia of rodents and was proved to act on the periventricular neural system and peripheral central nervous areas. Likewise, a human cerebrovascular endothelial cell line expressing FFAR3 lost its integrity post lipopolysaccharide (LPS) exposure, which was abolished after adding SCFAs (predominantly propionate) to the in vitro culture. Interestingly, a depletion of SCFAs was reported in MDD patients [75], and their administration was shown to alleviate symptoms of depression in mice [76]. Therefore, the analysis of the SCFAs concentration could serve as an indirect way to analyse microbiota composition, especially in the neuropsychiatric population. Given that bacterial functions are conserved across taxonomic groups, incorporating microbial function biomarkers like SCFAs may be more productive than a purely taxonomic approach for understanding of the microbiome in depression. Based on the above, we decided to assess faecal microbiota function through measurement of SCFAs concentrations concurrently with microbiota composition.

In conclusion, depression is one of the most disabling chronic diseases and impacts multiple domains of functioning. Additionally, depressive disorders often coexist with MetS further increasing mortality risks. Current treatments for both depression and MetS remain suboptimal for many patients, thus making improvements and advances in the intervention options in great demand. Whilst probiotics may have benefits for some individuals who do not fully respond to antidepressant medications, the target clinical sample for this intervention is not fully recognized. This clinical trial will investigate the influence of probiotic supplementation on depressive and anxiety symptoms in patients with depression depending on metabolic syndrome comorbidity. In addition, this trial will assess intestinal microbiota function and composition, inflammatory status markers and oxidative stress parameters as potential biomarkers of treatment efficacy. The trial, if successful, will establish a safe and easy-to-use treatment option (probiotic supplement) as an adjunctive therapy in patients only partially responsive to pharmacologic treatment. Given the personal and societal cost of treatment of civilization diseases, the research may contribute to advancement in offered health care over millions of people.

**Funding:** This research will be funded by the Medical University of Lodz grant number 503/1-155-02/503-11-003-20. The APC was funded by the Medical University of Lodz.

**Author Contributions:** Conceptualization, O.G.-K.; Methodology, O.G.-K., A.S., K.Cz.-Ch., K.S.-Ż.; Software, O.G.-K., A.M.; Formal Analysis, A.M.; Investigation, O.G.-K., A.M.; Resources, O.G.-K., A.S., A.M., K.Cz.-Ch., K.S.-Ż.; Writing – Original Draft Preparation, O.G.-K.; Writing – Review & Editing,
K.Cz.-Ch., A.M., K.S.-Ż., I.Ł.; Visualization, O.G.-K., K.Cz.-Ch.; Supervision, D.S.; Project Administration, O.G.-K., A.S.; Funding Acquisition, D.S.

Institutional Review Board Statement: The study was conducted according to the guidelines of the Declaration of Helsinki, and approved by the Institutional Ethics Committee of the Medical University of Lodz (reference number RNN/228/20/KE) on 15th December 2020.

Informed Consent Statement: Informed consent will be obtained from all the subjects involved in the study.

Conflicts of Interest: I.Ł. is a foundation shareholder in Sanprobi, a probiotics distributor. O.G.-K. and K.S.-Ż. received remuneration from Sanprobi. However, the content of this study was not constrained by this fact. The other authors declare that they have no competing interests.

Appendix A

Sample size analyses details

I. MADRS score

First of all, we assume that the distribution of MADRS scores (0-60 points) in the population of depressed and non-depressed individuals tends to be normal as it is in the case of BDRS according to the study by Bruschi et al [77]. In that study MADRS score has a mean of 27.5 and a standard deviation of 7.1. A difference in HDRS score of 3.5 or higher seems clinically relevant (then Cohen’s D has value of 0.43).

Using an online tool (stat.ubc.ca), we calculated a sample size (assuming that both groups taking part in the study are the same size). The total sample size for this study should be around 130 (M1=27.5, M2=24.0, SD=7.1, alpha=0.05, power=80%). If the total number is smaller, i.e., about 40 individuals per group, we get power value around 0.60.

We verified those numbers using Statistica 13. If the statistical values are as follows M1=27.5, M2=24.0, SD=7.1, n1=65, n2=65, power goal =0.80, then we get statistical significance of 0.006, while in the case of N=80, we get alpha=0.03 (power=0.58).

To sum up, ideally the required number of subjects is 65 per group, however, with 40 persons per group it still seems possible to detect a statistical difference in MADRS score between the groups.

II. SCFAs levels

First of all, we assume that the distribution of SCFAs levels in the population of depressed and non-depressed individuals tends to be normal as in the study by Farup et al. [78]. In that study, the sum of SCFA has a mean of 8.36 and a standard deviation of 7.57. A difference in SCFAs levels of 3.5 or higher seems clinically relevant (then Cohen’s D has value of 0.46).

Using an online tool (stat.ubc.ca), we calculated a sample size (assuming that both groups taking part in the study are the same size). The total sample size for this study should be around 148 subjects (M1=7.36, M2=10.86, SD=7.57, alpha=0.05, power=80%). If the total number is smaller, i.e., about 100 individuals, we get power value around 0.64.
We verified that numbers using Statistica 13. If the statistical values are as follows $M_1=7.36, M=10.86, SD=7.57, n_1=50, n_2=50$, power goal =0.80, then we get statistical significance of 0.02, while in the case of $N=288$, we get alpha=0.005. In the case of 40 subjects per group we can still achieve a statistically significant difference between the groups ($p = 0.042$), however with a lower statistical power (0.53).

To sum up, the ideal required number of subjects is 74 per group, however, with 40 persons per group it still seems possible to detect a statistical difference in SCFA levels between the groups.

**III. Alpha diversity**

First of all, the distribution of microbial diversity (alpha diversity) in the population of depressed and non-depressed individuals seems to be normal according to the study by Gonzalez et al [79]. In that study, alpha diversity has mean of 13.5 and a standard deviation of 3.45. A difference in alpha diversity of 1.5 or higher seems clinically relevant (Cohen’s $D$ has a value of 0.43, while a value higher than 0.4 is widely considered to be associated with clinically relevant effect size).

Using an online tool (stat.ubc.ca), we calculated a sample size (assuming that both groups taking part in the study are the same size). Total sample size for this study should be around 168 ($M_1=12.0, M_2=14, SD=3.45, alpha=0.05, power=80\%$). If the total number is smaller (about 100 individuals), we get power value around 0.58.

We verified those numbers using Statistica 13. If the statistical values are as follows $M_1=12.0, M_2=14, SD=3.45, n_1=50, n_2=50$, power goal=0.80, then we get statistical significance of 0.032, while in the case of $N=180$, we get alpha=0.004. In the case of 40 subjects per group, we can still achieve a statistically significant difference between the groups ($p = 0.01$), with a lower statistical power (0.73).

To sum up, ideally the population should be bigger than 84 people per group, however, with 40 persons per group, it still seems possible to detect a statistical difference regarding alpha diversity between the groups.

**Appendix B**

**Table 3. Characteristics of the ELISA assays used to assess the inflammation and oxidative stress parameters.**

**Horseradish Peroxidase (HRP)**

| Inflammation and oxidative stress parameters | Primary antibody | Secondary antibody | Volume of serum per patient/timepoint |
|---------------------------------------------|------------------|--------------------|--------------------------------------|
| IL-6 cytokine                               | Biotinylated Anti-IL-6 | Streptavidin-HRP***, colorimetric reaction with TNM substrate | 100μl x 2 repetitions |
| TNFα | polypeptide cytokine | Biotinylated Anti-TNFalpha | Streptavidin-HRP, colorimetric reaction with TNM substrate | 100μl x 2 repetitions |
|------|---------------------|---------------------------|----------------------------------------------------------|----------------------|
| MDA | Prostaglandin, enol | Biotinylated Anti-MDA     | Avidin-HRP, colorimetric reaction with TNM substrate      | 50μl x 2 repetitions |
| TAC | Total count of      |                           | photometrically by an enzymatic reaction which involves the conversion of TMB to a colored product, compared to the calibrator. | 50μl x 2 cond. x 2 repetitions |
