The aim of this study was to determine factors in favor of delaying tracheostomy in patients with acute respiratory failure related to COVID-19 for the first time wave of the pandemic in 2020 in the Netherlands, to ascertain whether timing of tracheostomy had an association with outcome, and to identify factors that had an association with timing.

Methods: Secondary analysis of the ‘PRactice of VENTilation in COVID-19’ (PRoVENT-COVID) study, a multicenter observational study, conducted from March 1, 2020 through June 1, 2020 in 22 Dutch intensive care units (ICU) in the Netherlands. The primary endpoint was the proportion of patients receiving tracheostomy; secondary endpoints were timing of tracheostomy, duration of ventilation, length of stay in ICU and hospital, mortality, and factors associated with timing.

Results: Of 1023 patients, 189 patients (18.5%) received a tracheostomy at median 21 [17 to 28] days from start of ventilation. Timing was similar before and after online publication of an amendment to the Dutch national guidelines on tracheostomy focusing on COVID-19 patients (21 [17–28] vs. 21 [17–26] days). Tracheostomy performed ≤ 21 days was independently associated with shorter duration of ventilation (median 26 [21 to 32] vs. 40 [34 to 47] days) and higher mortality in ICU (22.1% vs. 10.2%), hospital (26.1% vs. 11.9%) and at day 90 (27.6% vs. 14.6%). There were no patient demographics or ventilation characteristics that had an association with timing of tracheostomy.

Conclusions: Tracheostomy was performed late in COVID-19 patients during the first wave of the pandemic in the Netherlands and timing of tracheostomy possibly had an association with outcome. However, prospective studies are needed to further explore these associations. It remains unknown which factors influenced timing of tracheostomy in COVID-19 patients.

tracheostomy (counted as the number of days between start of invasive ventilation and tracheostomy procedure), outcomes including duration of ventilation, ICU— and hospital—length of stay (LOS), and ICU—, hospital—, and day 28— and day 90—mortality, and factors associated with timing.

National Dutch guidelines on tracheostomy

Before the pandemic, Dutch guidelines regarding tracheostomy practice in invasively ventilated ICU patients advised to ‘consider a tracheostomy as soon as it is apparent that weaning from artificial ventilation is unlikely to happen within 2 weeks after endotracheal intubation’, and also ‘because this prediction is difficult, it is advised to generally delay the procedure until at least 10 days after intubation’. The amendment focusing on tracheostomy in COVID—19 patients was released on April 23, 2020 and advised to wait at least 2 weeks before performing tracheostomy and if possible, to further delay the procedure to reduce the risk of viral transmission.

Statistical analysis

Continuous variables are presented as medians with interquartile ranges, and categorical variables as number and percentages. Timing of tracheostomy is shown in cumulative distribution plots stratified by (1) month of admission; (2) the median timing of tracheostomy of this cohort; and (3) admission before and after introduction of the amended national guideline.

Baseline characteristics and outcomes were compared between groups defined by tracheostomy status and by the median timing of this cohort. Wilcoxon rank—sum test for continuous variables and Fisher exact test for categorical variables were used accordingly. Duration of ventilation was compared through a clustered Fine—Gray competing risk model, with death before extubation treated as competing risk. Both survivors and non—survivors were included in this analysis. Binary outcomes were compared with adjusted odds ratios from a mixed—effect generalized linear model with a binomial distribution. Twenty—eight and 90—day mortality and ICU— and hospital—LOS were compared with adjusted hazard ratios from a Cox proportional hazard model. All models were adjusted for variables with a known or suspected relationship with outcome in COVID—19 patients, including age, gender, body mass index (BMI), partial arterial oxygen pressure to oxygen fraction (PaO2/FiO2) and plasma creatinine level at baseline, hypertension, diabetes mellitus, use of angiotensin converting enzyme inhibitors, use of angiotensin II receptor blockers, use of inotrope or vasopressor at start of ventilation, fluid balance, arterial pH, mean arterial pressure, heart rate, and respiratory system compliance at start of ventilation. The center and week of admission were considered as random effect. The group receiving tracheostomy and the group with timing greater than the median were used as references. In addition, duration of ventilation, LOS in survivors and 90—day mortality were compared using Kaplan—Meier estimators.

To ascertain which clinical factors had an independent association with timing of tracheostomy, a mixed—effect generalized linear model with Gaussian distribution and with center as random effect was used and reported as mean difference and 95% confidence interval (CI). The following variables with a known or suspected relationship with timing of tracheostomy were selected: 1) week of admission in participating hospital, the first week being determined by the date of the first COVID—19 admission in the ICU of that particular hospital; 2) demographic characteristics (age, gender, BMI, diabetes, hypertension, heart failure, asthma, and obstructive sleep apnea syndrome); 3) ventilatory and oxygenation variables in the first day after intubation or admission, aggregated as the median from a maximum of six assessments (tidal volume, positive end—expiratory pressure, respiratory system compliance, and PaO2/FiO2); 4) laboratory tests and vital signs in the first day after intubation or admission, aggregated as the median from a maximum of six assessments (arterial pH, lactate, creatinine, heart rate and mean arterial pressure); 5) organ support during the first day after intubation or admission (use of vasopressors, use of neuromuscular blocking agents (NMBA) and fluid balance); 6) use of prone positioning in the first 4 days of ventilation; 7) incidence of complications (thromboembolic events, acute kidney injury, use of RRT); 8) need of reintubation; and 9) being admitted after the online publication of the COVID—19 amendment to the Dutch national guidelines for tracheostomy. Missing data in predictors, when present in less than 5% of the patients, were imputed by the median.

In a post hoc analysis, we also examined whether the abovementioned variables were independently associated with performance of tracheostomy.

All analyses were conducted in R v.4.0.2 (R Foundation, Vienna, Austria) and significance level was set at 0.05.

Results

Patients

Between March 1 and June 1, 2020, 31 ICUs were invited for participation in the ProVENT—COVID study and 22 met inclusion criteria. Of 1340 screened patients, 1023 were included in the current analysis (eFig. 1); the main reasons for exclusion were not having received invasive ventilation, unknown tracheostomy status due to transfer to a non—participating hospital, or having received ventilation for something other than COVID—19.

Incidence of tracheostomy

Of 1023 patients, 189 patients (18.5%) underwent tracheostomy. Tracheostomized patients were more often males and more likely to have asthma. On the first day of ventilation, tracheostomized patients had a higher respiratory compliance and etCO2, and underwent longer duration of prone positioning (eTable 1). Performance of tracheostomy was independently associated with reintubation, pulmonary embolism, AKI and use of RRT. Additionally, tracheostomy was independently associated with longer duration of ventilation and lower ICU—, hospital—, and day 28— and 90—day mortality (eTable 2).
Timing of tracheostomy

Time between start of invasive ventilation and tracheostomy was median 21 [17–28] days. Time until tracheostomy in March (21 [16–28] days), April (23 [17–28] days) and May (22 [17–26] days) was similar and seemed unaffected by the online publication of the amendment (21 [17–28] vs. 21 [17–26] days) (Fig. 1).

Compared to patients who were tracheostomized > 21 days, patients who were tracheostomized ≤ 21 days had a lower plasma creatinine and higher respiratory compliance and were ventilated with a higher tidal volume at baseline (Table 1). Tracheostomy ≤ 21 days was independently associated with shorter duration of ventilation, but higher ICU–, hospital– and 90–day mortality (Table 2 and Fig. 2).

Factors associated with timing and performance of tracheostomy

None of the clinical factors were associated with timing of tracheostomy (eTable 3). In the post hoc analysis, independent predictors of performance of tracheostomy were asthma, respiratory system compliance, occurrence of thromboembolic complications, need for RRT and reintubation (eTable 4).

Discussion

The findings of this secondary analysis of the PRoVENT–COVID study can be summarized as follows: (1) roughly 1 in every 5 patients were tracheostomized, (2) median timing of tracheostomy was 21 days, and this remained after online publication of the amendment of the national guideline, (3) tracheostomy ≤ 21 days had an independent association with shorter duration of ventilation and higher mortality rates, and (4) timing was not influenced by clinical factors. In a post hoc analysis, asthma, respiratory system compliance, occurrence of thromboembolic complications, need for RRT and reintubation were associated with performance of tracheostomy.

This analysis has several strengths. First, it is one of the largest cohorts of COVID–19 patients in which tracheostomy practice was analyzed. Second, we used data captured over the entire first wave of the pandemic in the Netherlands, encompassing about 40% of all ICU patients admitted during
## Table 1  Baseline characteristics of patients receiving tracheostomy according to timing.

that time. Third, university, non-university, teaching and non-teaching centers were involved, increasing the generalizability of this study. Fourth, hospitals that were invited but did not participate were unable to do so only because of administrative and regulatory barriers, unrelated to the workload and possible lack of time on the ICU. This makes selection bias unlikely. Fifth, the exact date of publication of the tracheostomy guideline amendment was known, giving accurate insight into its influence on practice of tracheostomy. Sixth, our statistical analysis plan was published before analysis of the data, preventing reporting bias.

The incidence of tracheostomy in the current cohort of COVID-19 patients is slightly higher than in LUNG SAFE,15 a large service review in which 13% of ARDS patients received a tracheostomy.16 LUNG SAFE patients were ventilated for a shorter duration and represent a more heterogeneous population of ARDS patients, possibly explaining this difference. Also, thromboembolic complications and AKI are prevalent among COVID-19 ARDS patients,17,18 factors which were shown to be predictors of performing a tracheostomy in this study.

The timing of tracheostomy was substantially later in this study than in LUNG SAFE, which showed a median timing of 14 days.16 This may be due to the larger proportion of patients with moderate–severe ARDS seen in this study, as well as lower PaO$_2$/FiO$_2$ and use of higher PEEP at baseline. Placement of a tracheostomy canula can be unsafe in patients with severely compromised gas exchange because of the unavoidable loss in positive airway pressure, delaying the procedure until improvement of oxygenation is seen. In addition, tracheostomy could have been postponed by health care providers out of fear of viral transmission, preferably waiting for a decrease in viral load.

Practice of tracheostomy is difficult to compare to other cohorts of invasively ventilated COVID-19 patients because of the large variability seen in both incidence and timing in a number of identified studies. Incidence of tracheostomy in

$^a$ Groups defined by the median timing of this cohort.

$^b$ National guideline on practice of tracheostomy on COVID-19 patients published on April 23, 2020.

$^c$ First week determined as the week when the first patient was admitted in the center.

$^d$ Most recent measurement in 24 hours before intubation, or at ICU admission under invasive ventilation.
Invasive ventilated COVID–19 patients has been shown to range from 8 to 77%, 3,19–35 and mean or median timing from 4 to 23 days. 5,19,22,24,27–42 As many of these identified studies are single center, this may reflect differences in local practices irrespective of national guidelines. This idea is supported by the fact that most of the identified studies showed a timing of ≤ 14 days, 19,22,24,27,28,32,33,35,39,42 despite 90% of international guidelines recommending waiting at least 14 days before performing a tracheostomy in COVID–19 patients. 10 The timing in our cohort, however, is in line with the majority of international guidelines, as well as the amendment of national Dutch tracheostomy guidelines. Therefore, it is possible that international advice regarding tracheostomy practice, released early on in the pandemic of 2020, was followed even before publication of the amendment of national guidelines. As it was already national practice to delay tracheostomy until at least 10 days after intubation, it would not have been a significant change in mindset.

Earlier timing of tracheostomy had an association with shorter duration of ventilation in this cohort. Freeing the patient from the ventilator as soon as possible is particularly valuable when there is a surge of patients needing to be treated in a pandemic. However, earlier tracheostomy was also associated with a higher mortality. This association was found after correcting for factors possibly having an

RRT: renal replacement therapy; NMBA: neuromuscular blocking agent; ECMO: extracorporeal membrane oxygenation; ICU: intensive care unit

a Groups defined by the median timing of this cohort; group tracheostomized after 21 days is the reference.

b Assessed in the first four days of ventilation.

c Subdistribution hazard ratio from a Fine-Gray competing risk model with death before extubation in 28 days treated as a competing risk and with center as clustering effect.

d Odds ratio from a mixed-effect generalized linear model with a binomial distribution and with center as random effect.

e Hazard ratio from a (shared frailty) Cox proportional hazard model for the ICU and hospital length of stay analyses, all patients who died prior to discharge were assigned the maximum length of stay to account for death as a competing risk in this model) with center as frailty. P value for the Schoenfeld residuals; < 0.001 (ICU length of stay); < 0.001 (hospital length of stay); < 0.001 (90-day mortality)
independent association with outcome, such as hemodynamic and respiratory problems. It is likely that this association is the result of immortal time bias and not an actual cause and effect. This phenomenon is introduced when patients cannot experience a certain outcome during a period of follow-up. In this analysis, patients in the later tracheostomy group already had survived 21 days before being categorized. This period is quite long, which may have increased the magnitude of bias.

This study has limitations. We had 99 patients with an unknown tracheostomy status due to transfer to a non-participating hospital. In addition, we did not collect local guidelines on tracheostomy practice, making it unclear what decisions were precisely based on. Different approaches to clinical decisions from each center may have influenced outcomes. We didn’t collect data on PPE and tracheostomy kit shortages and cannot determine the effect this had on timing. Whether a surgical or percutaneous technique was used for placement of tracheostomy was not recorded, which could have given additional insight into tracheostomy practice in the Netherlands. Ventilation data was restricted to the first four days of admission and therefore are unknown directly before placement of tracheostomy. Furthermore, data regarding incidence of ventilator associated pneumonia (VAP), other infections and sepsis were not collected; as these factors could influence both timing of tracheostomy and outcome, this is a limitation. Finally, use of additional therapies such as antibiotics, steroids and anticoagulants is unknown in our cohort, which could also have influenced outcome.

**Conclusion**

This study gives insight into the practice of tracheostomy in invasively ventilated COVID-19 patients in the Netherlands. The results suggest that earlier timing of tracheostomy is associated with a shorter duration of ventilation, which would be of crucial benefit in overloaded ICUs. However, because this study also suggested a higher mortality in patients who received earlier tracheostomy, future studies are needed to determine whether earlier tracheostomy has a positive influence on outcome in COVID-19 patients. It
remains unclear which factors influenced timing of tracheostomy during the first wave of the pandemic.
