(Dated: July 8, 2021)

A consistent microscopic theory of superconductivity for strongly correlated electronic systems is presented within the extended \(t-J-V\) model where the intersite Coulomb repulsion and the electron-phonon interaction are taken into account. The exact Dyson equation for the normal and anomalous (pair) Green functions is derived for the projected (Hubbard) electronic operators. The equation is solved in the self-consistent Born approximation for the self-energy. We obtain the \(d\)-wave pairing with high-\(T_c\) induced by the strong kinematical interaction of the order of the kinetic energy \(\sim t\) of electrons with spin fluctuations which is much larger than the exchange interaction \(J\). The Coulomb repulsion and the electron-phonon interaction give small contributions for the \(d\)-wave pairing. These results support the spin-fluctuation mechanism of high-temperature superconductivity in cuprates previously proposed in phenomenological models.

I. INTRODUCTION

Since the discovery of the high-temperature superconductivity (HTSC) in cuprates by Bednorz and Müller[1] many theoretical models were proposed to reveal the mechanism of HTSC but a commonly accepted one is still lacking (see, e.g. [2, 3]). The main problem in a theoretical study of the cuprate superconductors is that strong electron correlations preclude application of the conventional Fermi-liquid approach in description of their electronic structure[4]. They are Mott-Hubbard (more accurately, charge-transfer) antiferromagnetic (AFM) insulators where the conduction band due to the strong Coulomb interaction splits into two subbands of singly-occupied and doubly-occupied states in the lattice. In this case conventional electronic operators cannot be used and composite or projected electronic operators for subbands should be introduced. To cope with the problem of unconventional character of the projected electronic operators various methods have been applied in investigation of strongly-correlated electronic systems (for a review see [5]).

The first model of strongly correlated electrons revealing superconductivity is the \(t-J\) model proposed by Anderson[6]. It can be derived from the Hubbard model in the strong correlation limit[7, 11]. In the \(t-J\) model superconductivity occurs at finite doping in the spin-liquid of resonating valence-bond states (RVB) due to the AFM superexchange interaction \(J\). The RVB scenario was considered later using the gauge theory[12], the mean-field \(t-J\) model with the renormalized hopping \(t\) and exchange interaction \(J\) parameters[13], the variational Monte Carlo method for Gutzwiller wave functions[14, 15]. In Ref. [16] the \(t-J\) model was formulated as an effective Hamiltonian for the hole-doped superconducting cuprates. Since then the low-energy electronic spectrum, superconductivity, spin excitations in cuprates have been considered within the \(t-J\) model by numerous authors.

Extensive numerical studies have been performed by various methods, such as Lanczos diagonalization of small clusters, quantum Monte Carlo simulations of two-dimensional lattices, cluster approximations (for reviews see [17-21] and references therein). A delicate balance between superconductivity and other instabilities, AFM, spin-density wave, charge-density wave, etc., was found[21].

To take into account strong Coulomb correlations in the Hubbard model the dynamical mean field theory (DMFT) was proposed[22, 24]. It was used to consider the Mott-Hubbard transition from a conventional metallic state to an insulating state. However, to study phase transitions to AFM state or superconductivity the theory should be generalized to take into account short-range correlations. It was done within the dynamical cluster approximation (DCA) formulated in the reciprocal space[25, 27] and the cluster DMFT (or cellular DMFT) where the impurity single-site in DMFT is replaced by a finite cluster of lattice sites (see, e.g., [28, 32]). In the cluster perturbation theory (CPT) an exact diagonalization of the electronic spectrum in a finite cluster (usually, 4x4 sites in the 2D model) is found and then coupling between of the clusters is taken into account[33-39]. A variational cluster approximation (VCA) was also proposed[40, 42] where it was shown that the CPT and the cellular DMFT are limiting cases of a more general cluster method. A two-particle self-consistent approach was developed in Refs. [43, 45]. To take into account short-range correlations a generalized DMFT approach was proposed in Refs. [46, 52]. In the theory a momentum dependent self-energy \(\Sigma_k(\omega)\) was included in addition to the DMFT single-site self-energy \(\Sigma(\omega)\). This approach permits to describe a pseudogap formation near the Fermi level of the quasiparticle band.

In cluster theories, it was possible to describe the electronic spectrum with formation of the pseudogap state and the arc-type Fermi surface at low doping. The \(d\)-wave
superconductivity was also found but it was difficult to disclose the mechanism of the pairing. The role of the intersite Coulomb repulsion and the electron-phonon interaction are also difficult to include in the cluster calculations. To cope with problems, analytical approaches were also considered in several studies using various approximations for strong CI within the Hubbard-type models.

To deal with the projected character of the electronic operators which imposes local constraints of no double occupancy of lattice sites in the $t$–$J$ model, the slave-boson (fermion) technique was proposed (see Ref. 53 and references therein). In the mean-field approximation (MFA), commonly used in this method, the local constraints are approximated by a global one, that reduces the problem to conventional fermions and bosons in the mean field. In Ref. 59 the slave-boson representation was considered beyond the MFA for the extended $t$–$J$ model. A kinetic-energy driven mechanism of superconductivity for the fermion-spin theory was proposed where the pairing of fermions is induced by spin excitations described by slave bosons. However, as in the conventional slave-boson theory the local constraint of no double occupancy was not treated rigorously.

Several other technique for strongly correlated systems were also proposed, as e.g., a continued fraction representation for the GFs in Ref. 60. It was used in studies of spin excitations and hole spectrum in Refs. 61, 62. We mention also a diagram method for the Hubbard model suggested in Refs. 63 as a site cumulants expansion in terms of hopping parameters. In this case a moderate to strong Hubbard repulsion can be considered. Using this technique in Ref. 64 the electronic spectrum was found in the one-loop approximation which shows the four-band structure as observed in numerical calculations. The strong coupling diagram technique was used in Ref. 65 for investigating the influence of spin and charge fluctuations on electron spectra of the 2D $t$–$U$ Hubbard model. A dual fermion approach was proposed in Refs. 66, 67.

A formally rigorous method to treat the unconventional commutation relations for the projected electronic operators is based on the Hubbard operator (HO) technique 69 (a generalization of the HO representation for non-canonical degrees of freedom is given in 70). The diagram technique for the HOs was developed to study the Hubbard and $t$–$J$ models 71, 72. A superconducting pairing due to the kinematical interaction in the Hubbard model in the limit of strong electron correlations ($U \to \infty$) was first considered in Refs. 73. In the lowest order diagrams for the two-particle vertex equation which is equivalent to the MFA for the superconducting order parameter gives only the $s$-wave pairing.

A technically simpler method in comparison with the diagram technique is the projection technique 74 in the equation of motion method for the Green functions (GFs) 77 based on the Mori memory function approach 78. Applying this method in terms of the HOs in Refs. 79, 80 the $d$-wave pairing for the $t$–$J$ model was found in the MFA. It was also shown that the $s$-wave pairing is prohibited since it violates the restriction of no double occupancy. Superconducting pairing in the singlet band of the Emery model was considered in Ref. 81. In Refs. 82, 83 the equations of motion method for the GFs in the composite operator representation, similar to the HOs, was used in studies of the Hubbard model in the limit of strong correlations. The electronic spectrum, spin excitations and phase transitions were analyzed.

The MFA in the first order projection technique was considered in many studies of electronic and spin-excitation spectra in more complicated $t$–$J$ models. In Ref. 86 a strong effect of the three-site interaction $H_3$ in the $t$–$J^*$ model on the $d$-wave superconductivity was stressed and a modification of the superconducting order parameter was found in Ref. 87. In Refs. 88, 89 the renormalized mean-field theory for the $t$–$J$ model was formulated and compared with experiments in cuprates was performed. Using the LDA and tight-binding approximation for the La$_{2-x}$Sr$_x$CuO$_4$ an effective $t$–$t''$–$J^*$ model was derived in Ref. 90. The model was used to study the Lifshitz quantum phase transitions and transformation of the Fermi surface with hole concentration. Influence of the interlayer tunneling $t_2$ on the electronic structure of the bilayer cuprates with hole concentration and strong magnetic fields was considered in Ref. 91. Superconducting $T_c$ and spin correlations within $t$–$t''$–$J^*$ model were found in Ref. 92. An effective model for electron-phonon and spin-phonon interactions in terms of the HOs was also proposed. The isotope effect in the $t$–$J^*$ model with electron-phonon coupling was discussed in Ref. 93 and in Ref. 92 for the bilayer cuprates. Superconductivity in the two subband $t$–$J$ model for the honeycomb lattice was considered recently in many publications. In ref. 94 the singlet order parameter for the $d+id'$ pairing was obtained and the superconducting $T_c$ as a function of doping was calculated.

In studies of electronic spectrum and superconductivity within the $t$–$J$ model in MFA the exchange interaction $J$ was considered as the origin of electron coupling to the spin system. To go beyond the MFA higher order contributions to electron interaction with spins should be considered. Applying the projection technique in the equation of motion method for the GFs in terms of the HOs a microscopic theory of spin-fluctuation superconducting pairing was proposed in Refs. 95, 96. The Dyson equation for the normal and anomalous GFs was derived where a new energy scale caused by the kinematical interaction of electrons with dynamical spin fluctuations were found. The interaction is determined by the kinetic energy of electrons given by the hopping parameter $t$, much larger then the exchange interaction $J$. Calculation of the normal part of the self-energy operator brings about the renormalization of the electronic spectrum where at low doping the pseudogap and the arc-type Fermi sur-
face appear \cite{99, 100}. Suppression of the quasiparticle weight in the equation for the superconducting gap results in lowering of the superconducting transition temperature \(T_c\), in comparison with the MFA results. Similar spin-fluctuation superconducting pairing was proposed in Ref. \cite{101}. The spin-fluctuation \(d\)-wave pairing induced by the hopping parameter \(t\) was obtained within the diagram technique for the HOs in the \(t-J\) model \cite{102, 103}.

A number of studies of the \(t-J\) model at low doping predict that doped holes dressed by strong AFM spin fluctuations propagate coherently as quasiparticle spin-polarons with a narrow band of the order of \(J\) (see, e.g., \cite{104, 105}). In Ref. \cite{106} the singlet superconducting pairing of spin-polarons on the AFM background was found.

The memory function approach was used in Refs. \cite{107, 108} to study the magnetic susceptibility in cuprates within the \(t-J\) model and to explain the emergence of the magnetic resonance mode. A theory of spin excitations within the relaxation-function approach for the dynamical spin susceptibility in the \(t-J\) model was developed in the normal \cite{112} and superconducting \cite{113} states. It was shown that the magnetic resonance mode is caused by a weak damping of the spin excitations close to the AFM wave vector and does not relate to the superconducting phase transition contrary to the theoretical description based on the spin-exciton model \cite{108, 114, 115}.

A possibility of HTSC mediated by AFM spin fluctuations as a “glue” for superconducting pairing was considered within phenomenological spin-fermion models in many publications (see, e.g., \cite{116–122} and references therein).

In the spin-fermion models the conventional Fermi-liquid approach was used where the kinematical interaction of electron with spin fluctuation is lost. In the theory a fitting parameter for electron interaction of electron with spin fluctuation is lost. In the spin-fermion models the conventional Fermi-liquid approach was used where the kinematical interaction of electron with spin fluctuation is lost. In this paper we consider superconducting pairing in the extended \(t-J\) model on a square lattice. To study strong electron correlations in the singly occupied subband of the \(t-J\) model one has to use the projected electron operators, as \(\tilde{a}_{i\sigma}^\dagger = a_{i\sigma}^\dagger (1 - N_{i\bar{\sigma}})\). Here \(a_{i\sigma}^\dagger\) is a creation electron operator on the lattice site \(i\) with spin \(\sigma/2\), \(\sigma = \pm 1\) (\(\bar{\sigma} = -\sigma\)) and \(N_{i\bar{\sigma}} = \tilde{a}_{i\sigma}^\dagger \tilde{a}_{i\sigma}\) is the number operator. The \(t-J\) model in the conventional notation reads:

\[
H = - \sum_{i\neq j, \sigma} t_{ij} \tilde{a}_{i\sigma}^\dagger \tilde{a}_{j\sigma} + \frac{1}{2} \sum_{i\neq j} J_{ij} \left( S_i S_j - \frac{1}{4} N_i N_j \right) + H_{e, ep}(1)
\]

where \(S_i^\sigma = (1/2) \sum_{s,s'} \sigma^\alpha_{s,s'} a_{i\sigma}^\dagger a_{is}\) are spin-1/2 operators, \(\sigma^\alpha_{s,s'}\) is the Pauli matrix. Here \(t_{ij}\) is the hopping parameter between \(i\) and \(j\) lattice sites and \(J_{ij}\) is the AFM exchange interaction. The intersite CI \(V_{ij}\) for electrons and EPI \(g_{ij}\) are taken into account by the Hamiltonian:

\[
H_{e, ep} = \frac{1}{2} \sum_{i\neq j} V_{ij} N_i N_j + \sum_{i,j} g_{ij} N_i u_j \tag{2}
\]

where \(u_j\) describe atomic displacements on the lattice site \(j\) for phonon modes.

The unconventional commutation relations for the projected electron operators result in the kinematical interaction. For instance, if we consider commutation relation for the projected electron creation \(\tilde{a}_{j\sigma}^\dagger\) and annihilation \(\tilde{a}_{i\sigma}\) operators,

\[
\tilde{a}_{i\sigma} \tilde{a}_{j\sigma}^\dagger + \tilde{a}_{j\sigma}^\dagger \tilde{a}_{i\sigma} = \delta_{ij} (1 - N_{i\bar{\sigma}}/2 + \sigma S_i^z) \tag{3}
\]

we observe that they are Fermi operators on different lattice sites but on the same lattice site they describe the kinematical interaction of electrons with charge \(N_{i\bar{\sigma}}\) and spin \(S_i^z\) fluctuations.
It is convenient to describe the projected electron operators by the Hubbard operators (HOs) \( \hat{a}_{i\sigma}^+ \), as, e.g., \( \hat{a}_{i\sigma}^+ = X_i^o \). Using the HOs, we write the Hamiltonian \( H \) in the form

\[
H = - \sum_{i\sigma,j\sigma} t_{ij} X_i^{o\sigma} X_j^{o\sigma} - \mu \sum_i X_i^{\sigma\sigma} + \frac{1}{4} \sum_{i\sigma\beta,j\sigma} J_{ij} \left( X_i^{\sigma\sigma} X_j^{\beta\beta} - X_i^{\beta\beta} X_j^{\sigma\sigma} \right) + H_{\text{c.e.p.}},
\]

(4)

where the HOs \( X_i^{\alpha\beta} = |i\alpha \rangle \langle i\beta| \) describe transitions from the state \( |i, \beta \rangle \) to the state \( |i, \alpha \rangle \) on the lattice site \( i \) for three electronic states: the unoccupied state \( (\alpha, \beta = 0) \) and two singly occupied states \( (\alpha, \beta = \sigma) \). The chemical potential \( \mu \) in (4) is determined from the equation for the average number of electrons:

\[
n = \langle N_i \rangle,
\]

(5)

where \( \langle \ldots \rangle \) is the statistical average with the Hamiltonian (4).

The number and spin operators in the HO representation read

\[
N_i = \sum_{\sigma} N_{i\sigma}, \quad N_{i\sigma} = X_i^{\sigma\sigma},
\]

(6)

\[
S_i^\sigma = X_i^{\sigma\sigma}, \quad S_i^z = (\sigma/2) (X_i^{\sigma\sigma} - X_i^{\sigma\bar{\sigma}}).
\]

(7)

The HOs satisfy the completeness relation \( X_i^{o\sigma} X_i^{o\sigma} + X_i^{\sigma\sigma} X_i^{\sigma\sigma} = 1 \), which shows that only one quantum state \( |i, \alpha \rangle \) on each lattice site \( i \) can be occupied and, therefore, rigorously preserves the constraint of no double occupancy. From the multiplication rules for the HOs \( X_i^{\alpha\beta} X_i^{\gamma\delta} = \delta_{\beta\gamma} X_i^{\alpha\delta} \) for Fermi-type operators \( X_i^{o\sigma} \) follow the commutation relations as in Eq. (3) for \( \hat{a}_{i\sigma} \), while for Bose-type operators such as the number (6) or the spin (7) operators the commutation relations read:

\[
\left[ X_i^{\alpha\beta}, X_j^{\gamma\delta} \right] = X_i^{\alpha\beta} X_j^{\gamma\delta} - X_j^{\gamma\delta} X_i^{\alpha\beta} = \delta_{ij} \left( \delta_{\beta\gamma} X_i^{\alpha\delta} - \delta_{\alpha\delta} X_i^{\gamma\beta} \right)
\]

(8)

These commutation relations determine the kinematically interaction for the HOs.

### B. Dyson equation

To discuss the electronic spectrum and superconducting pairing within the model (1) we consider the matrix GF (27)

\[
\hat{G}_{ij,\sigma}(t-t') = -i \theta(t-t') \langle \{ \Psi_{i\sigma}(t), \Psi_{j\sigma}^+(t') \} \rangle = \langle \{ \Psi_{i\sigma}(t), \Psi_{j\sigma}^+(t') \} \rangle,
\]

(9)

where \( \theta(x) \) is the Heaviside function, \( \{ A, B \} = AB + BA \), \( A(t) = \exp(iHt)A \exp(-iHt) \) \((h = 1)\), and we introduced HOs in the Nambu notation:

\[
\Psi_{i\sigma} = \begin{pmatrix} X_i^{o\sigma} \\ \Psi_{i\sigma}^+ \end{pmatrix}, \quad \Psi_{i\sigma}^+ = \begin{pmatrix} X_i^{o\bar{\sigma}} & X_i^{o\sigma} \end{pmatrix}.
\]

(10)

The Fourier representation in \((\mathbf{k}, \omega)\)-space is defined by the relations:

\[
\hat{G}_{ij,\sigma}(t-t') = \frac{1}{2\pi} \int_{-\infty}^{\infty} dt e^{-i\omega(t-t')} \hat{G}_{ij,\sigma}(\omega),
\]

(11)

\[
\hat{G}_{ij,\sigma}(\omega) = \frac{1}{N} \sum_{\mathbf{k}} \exp[\mathbf{k}(\mathbf{r}_1 - \mathbf{r}_j)] \hat{G}_{\sigma}(\mathbf{k}, \omega),
\]

(12)

where \( N \) is the number of lattice sites. The GF (9) is convenient to write in the matrix form

\[
\hat{G}_{\sigma}(\mathbf{k}, \omega) = \begin{pmatrix} G_{\sigma}(\mathbf{k}, \omega) & F_{\sigma}(\mathbf{k}, \omega) \\ F_{\sigma}^*(\mathbf{k}, \omega) & -G_{\sigma}(-\mathbf{k}, -\omega) \end{pmatrix},
\]

(13)

where \( G_{\sigma}(\mathbf{k}, \omega) \) and \( F_{\sigma}(\mathbf{k}, \omega) \) are the normal and anomalous parts of the GF (9).

To calculate GF (9) we use the projection technique in the equation of motion method (27). By differentiating the GF over the time \( t \) we get the following equation

\[
\omega \hat{G}_{ij,\sigma}(\omega) = \delta_{ij} \hat{Q}_{\sigma} + \langle \{ \hat{Z}_{i\sigma}, \Psi_{j\sigma}^+ \} \rangle_\omega,
\]

(14)

where \( \hat{Z}_{i\sigma} = [\Psi_{i\sigma}, H] \). The matrix \( \hat{Q}_{\sigma} \) is the average value of time-independent operators \( \hat{Q}_{\sigma} = \langle \{ \Psi_{i\sigma}, \Psi_{j\sigma}^+ \} \rangle \).

The diagonal matrix element is given by \( \langle \{ X_i^{o\sigma}, X_i^{o\sigma} \} \rangle = \langle X_i^{o\sigma} + X_i^{o\sigma} \rangle = 1 - (1/2) \langle N_{i\sigma} \rangle + \langle S_i^z \rangle \), while the off-diagonal matrix element \( \langle \{ X_i^{o\sigma}, X_j^{o\bar{\sigma}} \} \rangle = 0 \). Thus, in the paramagnetic state, \( \langle S_i^z \rangle = 0 \), the matrix

\[
\hat{Q}_{\sigma} = \hat{t}_0 Q, \quad Q = 1 - n/2,
\]

(15)

is the \( \sigma \)-independent unity matrix determined by the average number of electrons (5). Therefore, in the following equations this matrix can be replaced by the scalar \( Q \).

Now, we project the many–particle GF in (14) on the single–electron GF

\[
\langle \{ \hat{Z}_{i\sigma}, \Psi_{j\sigma}^+ \} \rangle_\omega = \sum_i \hat{E}_{i\sigma} \langle \{ \Psi_{i\sigma}, \Psi_{j\sigma}^+ \} \rangle_\omega + \langle \{ \hat{Z}_{i\sigma}^{\text{irr}}, \Psi_{j\sigma}^+ \} \rangle_\omega
\]

(16)

where we introduce the irreducible part of the operator \( \hat{Z}_{i\sigma} \):

\[
\langle \{ \hat{Z}_{i\sigma}^{\text{irr}}, \Psi_{j\sigma}^+ \} \rangle = \langle \hat{Z}_{i\sigma}^{\text{irr}} \rangle \Psi_{j\sigma}^+ + \Psi_{j\sigma}^+ \hat{Z}_{i\sigma}^{\text{irr}} \rangle = 0.
\]

(17)

This results in the equation for the matrix of electronic energy in the GMFA:

\[
\hat{E}_{ij,\sigma} = \langle \{ \Psi_{i\sigma}, H, \Psi_{j\sigma}^+ \} \rangle Q^{-1} = \left( \frac{\varepsilon_{ij} \Delta_{ij,\sigma}}{\Delta_{ij,\sigma} - \varepsilon_{ij}} \right),
\]

(18)

which in the Fourier representation reads:

\[
\hat{E}_{\sigma}(\mathbf{k}) = \frac{1}{N} \sum_{\mathbf{r}_1, \mathbf{r}_j} e^{-i\mathbf{k}(\mathbf{r}_1 - \mathbf{r}_j)} \hat{E}_{ij,\sigma} = \left( \frac{\varepsilon(\mathbf{k}) \Delta_{\sigma}(\mathbf{k})}{\Delta_{\sigma}(\mathbf{k}) - \varepsilon(\mathbf{k})} \right).
\]

(19)

Here \( \varepsilon(\mathbf{k}) \) is the electronic spectrum in the normal state and \( \Delta_{\sigma}(\mathbf{k}) \) is the gap in the superconducting state. The energy matrix (19) defines the zero–order GF:

\[
\hat{G}_{\sigma}^{(0)}(\mathbf{k}, \omega) = Q \frac{\hat{t}_0 + \varepsilon(\mathbf{k}) \hat{t}_3 + \Delta_{\sigma}(\mathbf{k}) \hat{t}_1}{\omega^2 - E^2(\mathbf{k})},
\]

(20)
where \(\hat{\tau}_1, \hat{\tau}_3\) are the Pauli matrices and \(E^2(k) = \epsilon^2(k) + \Delta^2_\sigma(k)\) is the energy of quasiparticle (QP) excitations in the superconducting state.

By writing the equation of motion for the irreducible part of the GF in \((10)\) \(\langle \hat{Z}_{\sigma}^{\text{irr}}(t) | \Psi^+_{\sigma}(t') \rangle\) with respect to the second time \(t'\) for the right–hand side operator \(\Psi^+_{\sigma}(t')\) and performing the same projection procedure as in \((10)\) we can obtain the Dyson equation for the GF \((9)\) in the form

\[
\tilde{G}_{ij\sigma}(\omega) = G_{ij\sigma}^0(\omega) + \sum_{k,l} \tilde{G}_{k\sigma}^0(\omega) Q^{-1} \tilde{S}_{k\sigma}(\omega) \tilde{G}_{ij\sigma}(\omega).
\]

The self–energy operator \(\tilde{S}_{k\sigma}(\omega)\) is given by the proper part of the scattering matrix that has no parts connected by the single zero-order GF \((20)\):

\[
\tilde{S}_{ij\sigma}(\omega) = \langle \hat{Z}_{\sigma}^{\text{irr}} | \hat{Z}_{j\sigma}^{\text{irr}} \rangle_{\omega} Q^{-1}.
\]

The self-energy operator can be written in the same form as the GF \((13)\):

\[
\tilde{G}_{i\sigma}(k, \omega) = \left( M_{i\sigma}(k, \omega) \Phi_{\sigma}(k, \omega) \right) - M_{i\sigma}(k, -\omega),
\]

where the \(M_{i\sigma}(k, \omega)\) and \(\Phi_{\sigma}(k, \omega)\) denote the respective normal and anomalous (pair) components of the self-energy operator. Therefore, for the single–electron GF \((9)\) we obtain an exact representation:

\[
\tilde{G}_{i\sigma}(k, \omega) = Q \{\omega \hat{\tau}_0 - \tilde{E}_{\sigma}(k) - \tilde{S}_{\sigma}(k, \omega)\}^{-1}.
\]

A formal solution of the matrix equation \((24)\) can be written in the form (cf. \((26)\)):

\[
\tilde{G}_{i\sigma}(k, \omega) = \frac{\omega Z_k(\omega) \hat{\tau}_0 + (\epsilon(k) + \xi_k(\omega)) \hat{\tau}_3 + \phi_{\sigma}(k, \omega) \hat{\tau}_1}{(\omega Z_k(\omega))^2 - (\epsilon(k) + \xi_k(\omega))^2 - \phi_{\sigma}^2(k, \omega)}.\]

The superconduction gap \(\phi_{\sigma}(k, \omega)\) is determined both by the GMFA function \(\Delta_\sigma(k)\) in Eq. \((19)\) and the anomalous self-energy component \(\Phi_{\sigma}(k, \omega)\) in Eq. \((23)\):

\[
\phi_{\sigma}(k, \omega) = \Delta_\sigma(k) + \Phi_{\sigma}(k, \omega).
\]

The QP excitation in the GMFA \((19)\) is determined by the static correlation functions and can be directly calculated as described in the next section. However, to calculate the self-energy matrix \((23)\) which describes inelastic scattering of electrons on spin, charge fluctuations and phonons one has to introduce an approximation for the many–particle GFs in \((23)\) as considered in Section 4.

### III. GENERALIZED MEAN-FIELD APPROXIMATION

#### A. Normal state

The normal state GF in the GMFA is given by Eq. \((20)\) for the zero gap function:

\[
G^0(k, \omega) = \langle \langle X_{k0}^0 | X_{0k}^0 \rangle \rangle_\omega = \frac{Q}{\omega - \varepsilon(k)}.
\]

To calculate the energy \(\varepsilon(k)\) we use the equation of motion for the HOS

\[
\left( \frac{d}{dt} + \mu \right) X_{i\sigma}^{00} = -\sum_{j,\sigma'} t_{ij} B_{i\sigma\sigma'} X_{j\sigma'}^{00} + X_{i\sigma}^{00} \sum_j g_{ij} u_{ij} + \frac{1}{\tau} \sum_{j,\sigma'} J_{ij} (B_{j\sigma\sigma'} - \delta_{\sigma\sigma'}) X_{i\sigma}^{00} + X_{i\sigma}^{00} \sum_j V(i, j) N_j(30)
\]

Here we introduced the Bose-like operator

\[
B_{i\sigma\sigma'} = \langle \{X_{i\sigma}^{00} + X_{i\sigma}^{\sigma\sigma} \} \delta_{\sigma\sigma'} + X_{i\sigma}^{\bar{\sigma}\sigma} \delta_{\sigma\bar{\sigma}}\rangle - \left( \frac{1}{2} \right) N_i + \sigma S_i^\sigma \delta_{\sigma\sigma'} + S_i^\bar{\sigma} \delta_{\sigma\bar{\sigma}},
\]

which describes electron scattering on spin and charge fluctuations caused by the kinematic interaction \((3)\). Using Eq. \((30)\) we calculate the matrix \(\varepsilon_{ij} = \langle \{X_{i\sigma}^{00}, H \} X_{j\sigma}^{00} \rangle \rangle^{-1} \) and for the electronic energy \(\varepsilon(k)\) obtain the relation:

\[
\varepsilon(k) = -4 t \alpha \gamma(k) - 4 t' \beta \gamma'(k) - 4 t'' \beta \gamma''(k)
\]

\[
- \frac{2 J}{N} \sum_q \gamma(k - q) N_{q\sigma} + \omega^{(c)}(k) - \mu,
\]

\[
\omega^{(c)}(k) = \frac{1}{N} \sum_q V(k - q) N(q),
\]

where the renormalization of the chemical potential \(\delta \mu\) in the GMFA we include in the definition of \(\mu\). Here \(t, t', t''\) are the hopping parameters between the first \(a_1 = \pm a_x, \pm a_y\), second \(a_2 = \pm (a_x \pm a_y)\), and third \(a_3 = \pm 2 a_x, \pm 2 a_y\) neighbors, respectively \((a_x = a_y = a\) - the lattice constants). The Fourier components of the hopping parameter \(t(k)\), CI \(V(k)\) and the exchange interaction \(J(k)\) are given by:

\[
t(k) = 4 t \gamma(k) + 4 t' \gamma'(k) + 4 t'' \gamma''(k),
\]

\[
V(k) = 4 V_1 \gamma(k) + 4 V_2 \gamma'(k),
\]

\[
J(k) = 4 J \gamma(k),
\]

where \(\gamma(k) = (1/2)(\cos k_x + \cos k_y), \quad \gamma'(k) = \cos k_x \cos k_y, \quad \gamma''(k) = (1/2)(\cos 2k_x + \cos 2k_y)\). For the interstitial CI for the first and the second neighbors, \(V_1\) and \(V_2\) in \((33)\), we take sufficiently small values \(V_1 = 0.3t\) and \(V_2 = 0.2t\) as shown in numerical calculations \((33)\). For the AFM exchange interaction \((33)\) we take \(J = 0.4t\). Below we take \(t = 0.4\) eV as the energy unit and put \(t = 1\).
The analytical equations (38), (39) which give the numerical calculations it is more convenient to use functions \( t \) and \( C \) depend on the AFM correlation length \( \xi/a = 1/\sqrt{3} \) at various hole concentrations \( \delta = 1 - n \).

| \( \delta \)  | 0.05 | 0.10 | 0.20 | 0.30 | 0.40 |
|------------|------|------|------|------|------|
| \( \xi = 1/\sqrt{3} \) | 4.5  | 3.2  | 2.2  | 1.8  | 1.6  |
| \( C_{1}(\xi) \) | -0.3 | -0.24| -0.17| -0.13| -0.1 |
| \( C_{2}(\xi) \) | 0.2  | 0.14 | 0.09 | 0.06 | 0.04 |
| \( C_{Q}(\xi) \) | 9.00 | 5.02 | 2.74 | 1.84 | 1.33 |
| \( \chi_{Q}(\xi) \) | 44.98| 25.11| 13.68| 9.21 | 6.64 |
| \( \alpha(\xi) \)  | -0.043| 0.11 | 0.31 | 0.45 | 0.56 |
| \( \beta(\xi) \)  | 0.9  | 0.8  | 0.75 | 0.74 | 0.76 |

The renormalization of the spectrum (32) caused by the AFM short-range correlations is determined by the parameters:

\[
\alpha = Q \left( 1 + C_{1}/Q^2 \right), \quad \beta = Q \left( 1 + C_{2}/Q^2 \right),
\]

where the spin correlation functions for the first and the next neighbors are:

\[
C_{1} = \langle S_{i} S_{i \pm x/a_y} \rangle = \frac{1}{N} \sum_{\mathbf{q}} \gamma_{i}(\mathbf{q}) C_{\mathbf{q}},
\]

\[
C_{2} = \langle S_{i} S_{i \pm x/a_y \pm y/a_x} \rangle = \frac{1}{N} \sum_{\mathbf{q}} \gamma'_{i}(\mathbf{q}) C_{\mathbf{q}}.
\]

For the spin correlation function \( C_{\mathbf{q}} = \langle S_{\mathbf{q}} S_{-\mathbf{q}} \rangle \) we take the model:

\[
C_{\mathbf{q}} = \frac{C_{\mathbf{Q}}}{1 + \xi^2 [1 + \gamma(\mathbf{q})]},
\]

where the parameter \( C_{\mathbf{Q}} \) is defined from the normalization condition \( \langle S_{\mathbf{q}} S_{\mathbf{q}} \rangle = (3/4)n = (1/N) \sum_{\mathbf{q}} C_{\mathbf{q}} \). The correlation functions have the maximum \( C_{\mathbf{Q}} \) at the AFM wave vector \( \mathbf{Q} = (\pi, \pi) \). In Ref. [112] the correlation functions \( C_{1} \) and \( C_{2} \) as a function of doping were calculated for the \( t-J \) model (see Fig. 1). To simplify the numerical calculations it is more convenient to use the analytical equations (38), (39) which give \( C_{1} \) and \( C_{2} \) close to that ones in Ref. [112]. The correlation functions depend on the AFM correlation length \( \xi \). For its dependence on the hole doping \( \delta \) we use an approximation \( \xi/a = 1/\sqrt{3} \) observed in neutron scattering experiments (see, e.g., [128]) and confirmed in the exact diagonalization study for finite clusters [129]. The values of correlation functions \( C_{1} \), \( C_{2} \), \( C_{\mathbf{Q}} \), the AFM correlation length \( \xi \), and parameters \( \alpha \), \( \beta \) for various hole doping \( \delta \) are given in Table I. The value of the normalization parameter \( \chi_{Q} = 2C_{\mathbf{Q}}/\omega_{s} \), \( \omega_{s} = J = 0.4 \), for the dynamical spin susceptibility in Eq. (64) is also given.

The electronic occupation number in the GMFA is determined by the zero-order GF [29]

\[
N(\mathbf{k}) = \frac{Q}{\exp[\varepsilon(\mathbf{k})/T] + 1}.
\]

The chemical potential in the GMFA is calculated from the equation:

\[
n = \frac{1}{N} \sum_{\mathbf{k}, \sigma} N(\mathbf{k}) = \frac{2 - n}{N} \sum_{\mathbf{k}} \frac{1}{\exp[\varepsilon(\mathbf{k})/T] + 1}.
\]

Eq. (41) proves that \( n \leq 1 \) in the singly-occupied band in the \( t-J \) model.

To reproduce the realistic electronic spectrum which shows the FS transition from the four-pockets at small doping to a large one with doping for the hopping parameter we take \( t' = 0.1t \), \( t'' = 0.2t \). For these parameters we obtain the electronic spectrum in Fig. 1 which is similar to calculated within the Hubbard model in Refs. [122, 124]. Note that at small doping \( \delta = 0.05 \) the electronic energy \( \varepsilon(\mathbf{k}) \) at the \( \Gamma(0,0) \) and \( M(\pi, \pi) \) points of the BZ are close induced by short-range AFM correlations as in the long-range AFM state. This renormalization of the spectrum results in the FS \( \varepsilon(\mathbf{k}_F) = 0 \) with four hole pockets in Fig. 2 at low doping. As discussed in Section IV A by taking into account the self-energy contribution in the GF [25] instead of the well defined in the GMFA electronic spectrum in Fig. 1 we observe a diffuse spectral density. At the same time, the FS in Fig. 2 at low doping. As discussed in Section IV A, by taking into account the self-energy contribution in the GMFA, the effective bandwidth, while the density of state at the FS is decreasing.
FIG. 2: (Color online) Fermi surface in the quarter of the BZ for \( \delta = 0.05 \) (red, dash-dotted line), \( \delta = 0.1 \) (black, dash line), \( \delta = 0.2 \) (brown, dotted line), \( \delta = 0.3 \) (blue, solid line).

The anomalous correlation function in the energy matrix of motion (30) for the gap function we find the relation

\[
\delta \sigma = 0.
\]

(46)

The constraint \( \langle X_i^{0\sigma^*} X_i^{0\sigma} \rangle = 0 \) is fulfilled for the \( d \)-wave gap \( \Delta_\sigma(q_x, q_y) = -\Delta_\sigma(q_y, q_x) \) in integration over \((q_x, q_y)\) in (46) for \( E(q_x, q_y) = E(q_y, q_x) \).

Therefore, we disregard \( t(q) \) contribution in Eq. (43) and obtain the gap equation in the form

\[
\Delta_\sigma = \frac{1}{N} \sum_q \left[ t(q) - J(q) - V(q) \right] \langle X_i^{0\sigma} X_j^{0\sigma*} \rangle.
\]

(47)

Solution of the linearized gap equation (47) with \( E(q) = \varepsilon(q) \) gives \( T_c \) as a function of doping for the \( d \)-wave pairing shown in Fig. 4. The maximal value of \( T_c^{max} \approx 0.02t \approx 100 \text{K} \) for zero CI is at hole concentration \( \delta \approx 0.14 \) for the maximal DOS at the FS. For conventional values of the hopping parameters without hole pockets on the FS, as, e.g., in Ref. [97], \( T_c^{max} \) is at \( \delta \approx 0.33 \), far away from the experimental values \( \delta \approx 0.16 \).

B. Superconducting state

The superconducting gap function \( \Delta_\sigma(k) \) in the zero-order GF (20) is determined by the Fourier component of the anomalous correlation function in the energy matrix (18): \( \Delta_{ij\sigma} = \langle \{X_i^{0\sigma}, H\} \rangle \rangle Q^{-1} \). Using the equation of motion (30) for the gap function we find the relation

\[
\Delta_\sigma(k) = \frac{1}{NQ} \sum_q \left[ 2E(q) - J(q) - V(q) \right] \langle X_i^{0\sigma} X_j^{0\sigma*} \rangle.
\]

(43)

The EPI gives no contribution in the GMFA. From the GF \( E_i(q, \omega) \) in Eq. (20) we obtain for the correlation function

\[
\langle X_i^{0\sigma} X_j^{0\sigma*} \rangle = -\frac{\Delta_\sigma(q)}{2E(q)} \tanh \frac{E(q)}{2T}.
\]

(44)

There are two pairing contributions in Eq. (43): the exchange interaction \( J(k - q) \) and the \( k \)-independent kinematic interaction \( t(q) \). The latter gives \( k \)-independent gap

\[
\Delta_\sigma = -\frac{2}{N} \sum_q t(q) \frac{\Delta_\sigma(q)}{2E(q)} \tanh \frac{E(q)}{2T}.
\]

(45)

which violates the constraint of no double occupancy (see Refs. [79, 124]). In particular,

\[
\langle X_i^{0\sigma^*} X_i^{0\sigma} \rangle = \frac{Q}{N} \sum_q \frac{\Delta_\sigma(q)}{2E(q)} \tanh \frac{E(q)}{2T} \neq 0.
\]

CI \( V(k - q) \) strongly suppresses \( T_c \). The effective coupling for the CI \( V_1 = 0.3 \) results in weak coupling, \( J - V_1 = 0.1 \), and extremely small \( T_c^{max} \approx 4t \times 10^{-4} \) in comparison with \( T_c^{max} \) for \( V_1 = 0 \) in Fig. 4. Such a strong reduction of \( T_c \) is explained by the unretarded character of both interactions, the exchange interaction \( J \) and CI. They act in the whole subband of the \( t-J \) model and there is no renormalization of CI as in the case of retarded electron-phonon interaction. In the MFA, commonly used for the \( t-J \) model, it is possible to explain quite high \( T_c \approx 100 \text{K} \) observed in experiments as was proposed by Anderson [6]. But taking into account the CI comparable with the exchange interaction \( J \), high \( T_c \) in cuprates cannot be realized.

The three-site interaction \( H_3 \) in the \( t-J^* \) model further results in decreasing of the effective AFM interaction, in the simplest MFA (14) \( J^* \approx J(n/2) \). A more accurate estimation of the three-site interaction \( H_3 \) in the \( t-J^* \) model in Ref. [89] has shown that the superconductivity temperature \( T_c^{max} \) for the \( d \)-wave pairing is strongly suppressed, approximately in 25 times, in comparison with
the original $t$–$J$ model. So, even without CI $V_1$ the superconducting $T_{\text{max}}$ is very small and many calculations performed in MFA for the original $t$–$J$ model, as e.g., in Ref. [10] where a good agreement with experiments in cuprates was claimed, cannot explain high-$T_c$ in cuprates.

To find the superconductivity in this case we should take into account the kinematical interaction in the anomalous self-energy $\Phi_\sigma(\mathbf{k}, \omega)$ in Eq. (23) as discussed in the next Section.

IV. SELF-ENERGY CALCULATION

In this section we consider the strong coupling approximation (SCA) by taking into account the self-energy contribution to the GFs in comparison to the weak-coupling approximation (WCA) in the GMFA discussed in the previous section.

The self-energy $\Phi_\sigma$ is determined by the many-particle GFs where the normal and anomalous (pair) components in the matrix $\Phi_\sigma$ are given by:

$$M_{ij}(t-t') = (1/Q) \langle \langle X_i^{0\sigma}(t)|H(t)|X_j^{0\sigma}(t') \rangle \rangle_{\mathbf{k}, \omega}$$

$$\Phi_{ij}(t-t') = (1/Q) \langle \langle X_i^{0\sigma}(t)|X_j^{0\sigma}(t') \rangle \rangle_{\mathbf{k}, \omega}$$

As follows from the equation of motion (30), the many-particle GFs in Eqs. (48), (49) describe propagation of the time-dependent many-particle correlation functions $X_i^{0\sigma}(t)$ in the proper part of the self-energy, having no parts connected by a skeleton diagram for a fermion and a boson with a full vertex. This distinction results in different type of approximations for the self-energy. In the diagram technique the vertex is calculated by a perturbation theory, while for the self-energy $\Phi_\sigma$ we have to use an approximation for the many-particle GFs. Here we use the SCBA which is similar to the non-crossing approximation in the diagram technique. In the approximations, a propagation for Fermi-like and Bose-like excitations is assumed to be independent between time $t$ and $t'$. The time-dependent many-particle correlation functions in the proper part of the self-energy, having no parts connected by a single-electron GF, therefore can be written as a product of fermionic and bosonic time-dependent correlation functions.

In particular, the contribution from the kinematical interaction, the first sum in the equation of motion (30), is given by the decoupling of two-time correlation functions:

$$\langle X_m^{0\sigma} B_{j\sigma}^+ | X_l^{0\sigma}(t) B_{i\sigma'}(t) \rangle$$

$$= \langle X_m^{0\sigma} X_l^{0\sigma}(t) \rangle \langle B_{j\sigma}^+ B_{i\sigma'}(t) \rangle,$$ (50)

$$\langle X_m^{0\sigma} B_{j\sigma}^+ | X_l^{0\sigma}(t) B_{i\sigma'}(t) \rangle$$

$$= \langle X_m^{0\sigma} X_l^{0\sigma}(t) \rangle \langle B_{j\sigma}^+ B_{i\sigma'}(t) \rangle.$$ (51)

The decoupling is performed on different lattice sites ($j \neq m, i \neq l$) which exclude correlations between different type of excitations. The same type of approximation for the fermion-phonon GF $\langle X_m^{0\sigma} u_j X_l^{0\sigma}(t) u_i(t) \rangle = \langle X_m^{0\sigma} X_l^{0\sigma}(t) \rangle \langle u_j u_i(t) \rangle$ directly reproduces the Eliashberg theory [120] of superconductivity for the electron-phonon model. The vertex correction to the EPI in the Eliashberg theory is small given by the parameter $\omega_{ph}/\mu$ where $\omega_{ph}$ is a phonon energy. In the SCBA the vertex correction to the spin-fluctuation interaction is also small, of the order of $\omega_s/\mu$, the spin-fluctuation energy $\omega_s$ which restricts the region of interaction, to the Fermi energy $\mu$.

The time-dependent single-particle correlation functions at the right-hand side in Eqs. (50) and (51) are calculated self-consistently using the corresponding full GFs.

Using the spectral representation for these GFs, we obtain the expressions for the normal and anomalous components of the self-energy (see Appendix):

$$M(\mathbf{k}, \omega) = \frac{1}{N} \sum_{q} \int_{-\infty}^{\infty} \frac{d\omega^q}{\pi} K^{(+)}(\omega, z, \mathbf{k}, \mathbf{q}) [-\text{Im} G(\mathbf{q}, z)]$$

$$\Phi_\sigma(\mathbf{k}, \omega) = \frac{1}{N} \sum_{q} \int_{-\infty}^{\infty} \frac{d\omega^q}{\pi} K^{(-)}(\omega, z, \mathbf{k}, \mathbf{q}) [-\text{Im} F_\sigma(\mathbf{q}, z)].$$ (52)

The kernel of the integral equations (50), (51) is determined by the relation (see Appendix):

$$K^{(\pm)}(\omega, z, \mathbf{k}, \mathbf{q}) = \int_{-\infty}^{+\infty} \frac{d\Omega}{2\pi} \frac{\text{tanh}(\Omega z/2T) + \coth(\Omega/2T)}{\omega - z - \Omega}$$

$$\times \left\{ |g_{sf}(\mathbf{k}, \mathbf{q})|^2 \text{Im} \chi_{sf}(\mathbf{k} - \mathbf{q}, \Omega) \right\}$$

$$\pm \left\{ |g_{ph}(\mathbf{k} - \mathbf{q})|^2 \text{Im} \chi_{ph}(\mathbf{k} - \mathbf{q}, \Omega) \right\}$$

$$+ \int_{-\infty}^{+\infty} \frac{d\Omega}{2\pi} \frac{\text{tanh}(\Omega z/2T) + \coth(\Omega/2T)}{\omega - z - \Omega} \chi^{(\pm)}(\mathbf{k}, \mathbf{q}, \Omega),$$ (54)

where $|g_{sf}(\mathbf{k}, \mathbf{q})|^2 = |t(\mathbf{q})| (1/2) J(\mathbf{k} - \mathbf{q})^2$. The spectral densities of bosonic excitations are determined by the dynamic susceptibility for spin $\text{S}_{\mathbf{q}}$, number (charge) $\delta N_{\mathbf{q}} = N_{\mathbf{q}} - \langle N_{\mathbf{q}} \rangle$, and lattice (phonon) $u_{\mathbf{q}}$ fluctuations

$$\chi_{sf}(\mathbf{q}, \omega) = -\langle \text{S}_{\mathbf{q}} \text{S}_{-\mathbf{q}} \rangle \omega,$$ (55)

$$\chi_{cf}(\mathbf{q}, \omega) = -\langle \delta N_{\mathbf{q}} \delta N_{-\mathbf{q}} \rangle \omega,$$ (56)

$$\chi_{ph}(\mathbf{q}, \omega) = -\langle u_{\mathbf{q}} u_{-\mathbf{q}} \rangle \omega.$$ (57)

They are defined by the commutator GFs for the spin $\text{S}_{\mathbf{q}}$, number $\delta N_{\mathbf{q}} = N_{\mathbf{q}} - \langle N_{\mathbf{q}} \rangle$, and lattice displacement (phonon) $u_{\mathbf{q}}$ operators. At first we consider solution of these equations for the normal state.
A. Normal state GF

The normal state GF in Eq. (23) can be written as

\[ G(k, \omega) = \langle X^\sigma_0 | X^\sigma_k \rangle = \frac{Q}{\omega - \epsilon(k) - M(k, \omega)} \]  

(58)

where the normal state self-energy is given by Eqs. (52), (54). The spectral density of electronic excitation is determined by

\[ A(k, \omega) = -\frac{1}{\pi} \text{Im} G(k, \omega + i\epsilon) = \frac{-M''(k, \omega)/\pi}{[\omega - \epsilon(k) - M''(k, \omega)]^2 + [M''(k, \omega)]^2} \]  

(59)

Here we introduce the real, \( M'(k, \omega) \), and imaginary, \( M''(k, \omega) \), parts of the self-energy: \( M(k, \omega + i\epsilon) = M'(k, \omega) + iM''(k, \omega) \).

The renormalization parameter \( \lambda(k) \) for the electronic energy close to the FS, \( \omega \to 0 \), reads:

\[ Z_k(0) = 1 - [\partial M(k, \omega)/\partial \omega]_{\omega=0} \equiv 1 + \lambda(k), \]  

(60)

where \( \lambda(k) \) is the coupling parameter.

B. Superconducting state

The superconduction gap in the SCA (28) is determined both by the GMFA function \( \Delta_\sigma(k) \) (117) and the anomalous self-energy component \( \eta(k) \) (53) and (54). For calculation of superconducting \( T_c \) we can use the linear approximation for the anomalous GF in Eq. (63):

\[ F_\sigma(k, \omega) = \frac{Q}{2\omega} \frac{\phi_\sigma(k, \omega)}{Z_k^2(\omega) [\omega^2 - \bar{\epsilon}(k, \omega)]}, \]  

(61)

where the renormalized energy \( \bar{\epsilon}(k, \omega) = [\epsilon(k) + \xi_k(\omega)]/Z_k(\omega) \). Further we consider the gap equation close to the FS, \( \omega = 0 \):

\[ \phi_\sigma(k) = \frac{1}{N} \sum_q \int_{-\infty}^{+\infty} \frac{dz}{\pi} \left[ \frac{V(k - q) - J(k - q)}{\exp(z/T) + 1} \right], \]

\[ + K(-)(0, z, k, q) \left[ -\text{Im} \int Z_k(0) \left[ (z + i\epsilon)^2 - \bar{\epsilon}(q, z) \right] \right]. \]  

(62)

Solution of this equation we consider in Section V C.

V. RESULTS AND DISCUSSION

A. Model parameters

To perform numerical calculations we should introduce susceptibility models. For the spin-fluctuation susceptibility \( \chi_{s}(q) \) we use the model:

\[ \text{Im} \chi_s(q, \omega + i\epsilon) = \chi_s(q) \chi''(\omega) = \frac{\chi_Q}{1 + \xi^2(1 + \gamma(q))} \tanh \frac{\omega}{2T} \frac{1}{1 + (\omega/\omega_s)^2}. \]  

(63)

The model describes the broad energy spectrum of spin fluctuations \( \chi''(\omega) \) with the cut-off frequency \( \omega_s \) and the static susceptibility \( \chi_s(q) \) with the maximum at the AFM wave-vector \( Q = (\pi, \pi) \) as observed in the paramagnetic phase. Similar model was suggested in Ref. [100]. In Ref. [112] we have calculated the dynamic spin susceptibility for the \( t - J \) model which frequency and wave-vector dependencies are close to the model (63). It can be used in numerical calculations but it is more convenient to adopt the analytical model (63).

The intensity of electron interaction with spin fluctuations is determined by the maximum of the static susceptibility \( \chi_s(q) \) at \( Q = (\pi, \pi) \):

\[ \chi_Q = \frac{3n}{2\omega_s} \left\{ \frac{1}{N} \sum_q \frac{1}{1 + \xi^2(1 + \gamma(q))} \right\}^{-1}. \]  

(64)

It is very important that \( \chi_Q \) is not a fitting parameter but is fixed by the normalization condition:

\[ (S_l^2) = \frac{1}{\pi} \sum_{\omega = -\infty}^{+\infty} \frac{\chi''(\omega) d\omega}{\exp(\omega/T) - 1} \frac{1}{N} \sum_q \chi_s(q) \]  

(65)

that yields \( \chi_Q = 2C_Q/\omega_s \) presented in Table I. Therefore, there are two parameters which determine the function (63): the AFM correlation length \( \lambda \) that depends on the hole concentration \( \delta \) as given in Table II and the frequency \( \omega_s \). The latter can be estimated as \( \omega_s = J = 0.4t \) taking into account theoretical calculations, e.g., Refs. [100, 112], and experimental results of the inelastic magnetic neutron scattering experiments and optical measurements. As shown in Table I at large correlation length \( \xi \), low doping, the spin-fluctuation interaction given by \( \chi_Q \) is strong while with doping and decreasing \( \xi \) the interaction becomes weak.

For the EPI we can use the model of forward scattering. It can explain a weak transport EPI \( \lambda_{tr} \), while it may result in a strong superconducting coupling \( \lambda \), e.g., \( \lambda_{tr} < \lambda/3 \) [131]. To take into account the importance of the forward scattering we consider a model EPI for optic phonons in Eq. (63) suggested in Ref. [132]:

\[ |g_{ep}(k - q)|^2 \chi_{ph}(\omega) = g_{ep} \frac{\xi_{ch}}{1 + \xi_{ch}^2 |k - q|^2} \frac{\omega_0^2}{\omega_0^2 - \omega^2}. \]  

(66)

where \( \omega_0 = 0.1t \) is an optic excitation frequency. The parameter \( \xi_{ch} \) is the charge correlation length for holes and can be approximated by the relation \( \xi_{ch}/a = 1/(2\delta) \) [133]. This results in a large EPI in the underdoped case, while in the overdoping region it decreases, e.g., for \( qa = 0.1 \) it changes from 4 to 1.62 at \( \delta = 0.3 \). We assume a large EPI coupling constant \( g_{ep} = 8t = 3.2 \text{ eV} \).

For the charge susceptibility [60] we use the model considered in our calculation of the charge density waves.
in Ref. [134]:

\[ \chi_{sf}(q, \omega) = \frac{4}{\Omega_q^2 - \omega^2} \frac{1}{N} \sum_{q'} [t(q') - t(q - q')] N(q), \]

\[ \Omega_q^2 = \frac{2}{N} \sum_{q'} [t(q') - t(q - q')] \]

(67)

where the electronic occupation number \( N(q) \) we calculate in the GMFA [114].

We perform numerical calculations for the same parameters as for the electronic spectrum in Section III A and given in the Table I. The calculations are done for low temperature \( T = 0.02 \) which is much less than the chemical potential and the exchange interaction \( J = 0.4 \) so we can neglect temperature dependence of the correlation length and the electronic spectrum.

B. Normal state

Electronic spectrum in the normal state is determined by the spectral density \( \varepsilon(k, \omega) \). To calculate it we should find the self-energy \( \Sigma(k, \omega) \) given by Eq. (54):

\[ M(k, \omega) = \frac{1}{2\pi N} \int_{-\infty}^{+\infty} \int_{-\infty}^{+\infty} dz d\Omega \lambda^{\dagger}(k, q, \Omega) A(q, z). \]

(68)

We calculate the self-energy and the spectral density by iteration. In the lowest order for the spectral density \( A^{(0)}(q, z) = \delta(z - \varepsilon(q)) \) the first order of the imaginary part of the self-energy reads

\[ \frac{-1}{\pi} \text{Im} M^{(1)}(k, \omega + i\epsilon) = \frac{1}{2\pi N} \sum_q \lambda^{\dagger}(k, q, \omega - \varepsilon(q)) \]

\[ \times \left[ \tanh \frac{\varepsilon(q)}{2T} + \coth \frac{\omega - \varepsilon(q)}{2T} \right]. \]

(69)

The real part of the self-energy \( \text{Re} M(k, \omega) \) is calculated using the dispersion relation for the GFs \( \chi(k, \omega) \). The \( n \)-order of the self-energy \( M^{(n)}(k, \omega) \) is calculated using the \( (n-1) \)-order of the spectral density \( A^{(n-1)}(q, \omega) \). The iteration procedure converges for \( n > 8 \) and we present the results of calculations in the \( n = 10 \)-order of iterations. For the interactions in Eq. (54) we calculate separately contributions to the imaginary part of the self-energy determined by spin fluctuations \( M_{sf}(k, \omega) \), phonons \( M_{ph}(k, \omega) \) and charge fluctuations (CF) \( M_{cf}(k, \omega) \).

Let us consider the contribution to the self-energy \( \text{Re} M^{(1)}(k, \omega) \) produced by spin fluctuations. For the model \( [63] \) the first order of the imaginary part \( \text{Im} M^{(1)}(k, \omega) \) is given by

\[ \frac{-1}{\pi} \text{Im} M^{(1)}_s(k, \omega) = \frac{1}{2\pi N} \sum_{q} \frac{|g_{sf}(k, q)|^2 q \chi Q}{1 + \xi^2(1 + \gamma(k - q))} \]

\[ \times \left[ \tanh \frac{\varepsilon(q)}{2T} \tanh \frac{\omega - \varepsilon(q)}{2T} + \frac{1}{1 + (\omega - \varepsilon(q))/\omega_i} \right]. \]

(70)

As we show later, contributions to the imaginary part of the self-energy from phonons and CF are much smaller than from spin-fluctuations. Therefore, we can neglect these contributions and in the iteration procedure for the self-energy and the spectral density use \( M_{sf}(k, \omega) \) and \( A_{sf}(k, \omega) \).

The results of the 10-th order of iterations for the spectral density \( A_{sf}(k, \omega) \) and the energy dispersion \( \varepsilon(k) \) obtained by 2D projection of \( A_{sf}(k, \omega) \) along the main directions in the BZ, \( \Gamma(0, 0) \rightarrow X, (\pi, 0) \rightarrow M(\pi, \pi) \rightarrow \Gamma(0, 0) \) for \( \delta = 0.05 \).

FIG. 5: Spectral density \( A(k, \omega) \) along the main directions in the BZ: \( \Gamma(0, 0) \rightarrow M(\pi, \pi) \rightarrow X(\pi, 0) \rightarrow \Gamma(0, 0) \) for \( \delta = 0.05 \).

FIG. 6: Energy dispersion along the main directions in the BZ: \( \Gamma(0, 0) \rightarrow X(\pi, 0) \rightarrow M(\pi, \pi) \rightarrow \Gamma(0, 0) \) for \( \delta = 0.05 \).

At low dop-
citation energy caused by the real part of the self-energy. Therefore, we can conclude that the self-energy effects are very important in studies of the QP excitations in the t-J model.

The QP damping determined by the imaginary part of the self-energy \( \Gamma(k, \omega) = -(1/\pi)\text{Im}M_{sf}(k, \omega) \) due to spin-fluctuation interaction is plotted in Fig. 11 at doping \( \delta = 0.1 \). For a larger doping, \( \delta = 0.3 \), the intensity decreases as shown in Fig. 12. A large asymmetry of the damping for the hole spectrum below the Fermi energy, \( \omega < 0 \), and for the electron spectrum at \( \omega > 0 \) is observed with a strong damping for the hole spectrum. In Fig. 12 for \( \delta = 0.3 \) it is shown more clearly. Strong damping

for the hole spectrum results in a large incoherent background in the spectral density \( A(k, \omega) \) in Figs. 6 - 10. Close to the Fermi energy the damping \( \Gamma(k, \omega \rightarrow 0) \) disappears linearly with \( \omega \) for a small doping as in Fig. 11 while for a large doping it proportional to \( \omega^2 \) as in Fig. 12. This behavior looks like as a transition from the marginal Fermi-liquid to the conventional Fermi-liquid.
In comparison with other studies we can mention the spectrum of excitations for the $t$-$J$ model obtained within the CPT in Ref. [38] (see Fig.1 (b-d)). The spectrum is close to our results, in particular, a flat dispersion for the energy excitations with high intensity close $X(\pi, 0)$ point of the BZ is clearly reproduced in our figures. Studies of the spectral properties for the two-dimensional $t$-$J$ model using the finite-temperature Lanczos method in Ref. [133] have revealed similar results for the spectral density and the imaginary part of the self-energy. The spectrum of the hole excitations found in the Hubbard model reproduces the main features of the spectrum in the $t$-$J$ model as was found within the equation of motion method in Refs. [122], [123] and applying the CPT in Ref. [39].

The EPI contribution (66) for the imaginary part of the phonon self-energy $M_{ph}(k, \omega)$ (69) reads:

$$-\frac{1}{\pi} \text{Im} M_{ph}(k, \omega) = \frac{1}{2\pi N} \sum_{q} \frac{g_{\text{ep}} \xi_{ch}}{1 + \xi_{ch} |k - q_{c}|^2}$$

$$\times \int_{-\infty}^{+\infty} dz \left[ \tanh \frac{z}{2T} + \coth \frac{\omega - z}{2T} \right] \text{Im} A(q, z) \omega^2_{0}$$

(71)

The frequency dependence of the imaginary part of the phonon self-energy is shown in Fig. 13 for $\delta = 0.1$. For the spectral density we used $A_{sf}(q, z)$. The CF contribution

FIG. 13: Imaginary part of the phonon self-energy $-(1/\pi)\text{Im} M_{ph}(k, \omega)$ for $\delta = 0.1$.

for the imaginary part of the self-energy $M_{sf}(k, \omega)$ (69) is given by

$$-\frac{1}{\pi} \text{Im} M_{sf}(k, \omega) = \frac{1}{2\pi N} \sum_{q} \left[ |V(k - q)|^2 + \frac{1}{4} |t(q)|^2 \right]$$

$$\times \int_{-\infty}^{+\infty} dz \left[ \tanh \frac{z}{2T} + \coth \frac{\omega - z}{2T} \right] A(q, z) \text{Im} \chi_{sf}(k - q, \omega - z)$$

(72)

The imaginary part of the CF self-energy is plotted in

FIG. 14: Imaginary part of the charge fluctuation self-energy $-(1/\pi)\text{Im} M_{sf}(k, \omega)$ for $\delta = 0.1$.

The phonon and CF contributions are an order of magnitude smaller than the imaginary part of the spin-fluctuation self-energy and, therefore, can be ignored in calculation of the spectral density. Therefore, the results obtained for the spin-fluctuation spectral density $A_{sf}(k, \omega)$ can be considered as the total spectral density $A(k, \omega)$ (59). The DOS $A(\omega)$ in the SCA is determined

FIG. 15: (Color online) Density of states $A(\omega)$ for $\delta = 0.05$ (red, dash-dotted line), $\delta = 0.1$ (black, dashed line), $\delta = 0.2$ (brown, dotted line), $\delta = 0.3$ (blue, solid line).

by the function

$$A(\omega) = \frac{1}{N} \sum_{k} \frac{1}{\pi Q} [-\text{Im} G(k, \omega)] = \frac{1}{N} \sum_{k} A(k, \omega),$$

(73)

and presented in Fig. 15 in units of $1/t$ for various doping.

In comparison with the DOS $A^{(0)}(\omega)$ in the GMFA in Fig. 3, $A(\omega)$ in the SCA shows lower values for small doping at the FS due to a small QP weight $1/Z_{k}$ at low doping. The results of spectral density close to the Fermi surface $A(k, \omega = 0)$ (59) which determines the FS are presented in Figs. 16–18. The FS changes from the arc-type at low doping ($\delta = 0.05, 0.1$ ) as demonstrated in Figs. 16-17 to the large FS at high doping ($\delta = 0.3$) in Fig. 18. In the GMFA, we have well-defined quasiparticles
nalization studies for the $t$-$t'$-$t''$-$J$ model. At low hole concentration $\delta = 0.1$ a gap opening occurs in this region leading to arcs on the FS. The arc type FS were obtained using the CPT for the $t$-$J$ model in Ref. [38] and for the Hubbard model in Ref. [39].

In ARPES experiments in cuprates only the arc transformation at low doping to large FS is observed since a weak intensity of the inner part of the pockets makes them invisible. In particular, in Ref. [137], the FS show the arcs at doping $x = 0.05, 0.1$ which can be considered as a manifestation of the pockets where only the outer part of it is found. Similar results were obtained in other publications, see Ref. [138] where large intensity of the ARPES signal at the "arc-type" part of the FS in the underdoped regime and the large FS in overdoped regime were obtained. In Ref. [139] two gaps were found, one is the PG region outside the arcs and the SC gap related to arcs. In Ref. [140] well defined arcs on the FS with underlying FS are obtained.

The wave-vector and doping dependence of the QP renormalization parameter $Z_k$ [60] calculated from the real part of the self-energy is shown in Fig. 19. It strongly depends on the doping being especially large for low doping resulting in a small QP weight $1/Z_k$.

C. Superconducting state

The gap equation (62) close to the FS defined by the function $K(0, z, k)$ [54] can be written as

$$\phi_\sigma(k) = \frac{1}{N} \sum_q [J(k - q) - V(k - q)] \frac{\phi_\sigma(q)}{2Z^2 q^2(q)} \frac{\tanh(x)}{2T_c}$$

$$- \frac{1}{N} \sum_q +\infty +\infty \int_0^\infty dz d\Omega \frac{\tanh(z/2T_c) + \coth(\Omega/2T_c)}{2\pi} \phi_\sigma(q)$$

$$\times \lambda^{-1}(k, q, \Omega) \frac{-\Im[H_0(q, \sigma)]}{Z^2} \frac{1}{Z^2 |z^2 - \tilde{\varepsilon}(q)|},$$

where the first term is the integrated over $z$ in (62) the GMFA gap function. The second order contributions are
determined by the function:
\[
\lambda^{(-)}(k, q, \Omega) = \left\{ |g_{sf}(k, q)|^2 \Im\chi_{sf}(k - q, \Omega) \\
-g_{ep}(k - q)^2 \Im\chi_{ph}(k - q, \Omega) \\
-\left| V(k - q) \right|^2 + \left| t(q) \right|^2 4 \Im\chi_{sf}(k - q, \Omega) \right\} = -\sum_{\alpha} |g_{\alpha}(k, q)|^2 \Im\chi_{\alpha}(k - q, \Omega), \tag{75}
\]
where \(\alpha = sf, ph, cf\). After integration over \(z\) of the second term in (74) for the \(\alpha\)-component of this term we obtain:
\[
\phi_{\sigma}^\alpha(k) = \frac{1}{N} \sum_{q} \frac{\phi_{\sigma}(q)|g_{\alpha}(k, q)|^2}{2Z_\sigma^2 q^{2}} \int_{-\infty}^{+\infty} \frac{d\Omega}{2\pi} \frac{\Im\chi_{\alpha}(k - q, \Omega)}{\Omega^2 - \tilde{\epsilon}(q)^2} \left[ 2\Omega \tanh \left( \frac{\tilde{\epsilon}(q)}{2T} \right) - 2\tilde{\epsilon}(q) \coth \left( \frac{\Omega}{2T} \right) \right]. \tag{76}
\]
Here summation over \(q\) is performed for the electronic energy \(\tilde{\epsilon}(q)\) close to the Fermi energy \(\tilde{\epsilon}(q) = 0\) in the narrow region \(\tilde{\epsilon}(q) < \Omega\). The bosonic excitation energy \(\Omega\) is determined by the dynamic susceptibility \(\Im\chi_{\alpha}(k - q, \Omega)\). In this approach we can take the electronic energy \(\tilde{\epsilon}(q) = 0\) in the denominator \(\Omega^2 - \tilde{\epsilon}(q)^2\) of Eq. (76) and neglect the contribution from the bosonic excitations given by \(\tilde{\epsilon}(q)\) \(\coth(\Omega/2T)\). In this approximation Eq. (75) reads:
\[
\phi_{\sigma}^\alpha(k) = \frac{1}{N} \sum_{q} |g_{\alpha}(k, q)|^2 \chi_{\alpha}(k - q, \Omega) \frac{\phi_{\sigma}(q)}{2Z_\sigma^2 q^{2}} \tanh \left( \frac{\tilde{\epsilon}(q)}{2T} \right) \tag{77}
\]
where we took into account the dispersion relation for the susceptibility \(\int_{-\infty}^{+\infty} (d\Omega/\pi \Omega) \Im\chi_{\alpha}(k - q, \Omega) = \Re\chi_{\alpha}(k - q, 0)\) and introduced the static susceptibility \(\chi_{\alpha}(k - q) = \Re\chi_{\alpha}(k - q, 0)\). Therefore, the gap equation (74) for \(\phi_{\sigma}(k) = \sigma\phi(k)\) takes the form
\[
\phi(k) = \frac{1}{N} \sum_{q} \frac{\phi(q)}{2Z_\sigma^2 q^{2}} \tanh \left( \frac{\tilde{\epsilon}(q)}{2T} \right) \times \left\{ J(k - q) - V(k - q) - \left| t(q) \right|^2 \chi_{sf}(k - q) \theta(\omega_s - |\tilde{\epsilon}(q)|) + \left| g_{ep}(k - q) \right|^2 \chi_{ph}(k - q) \theta(\omega_0 - |\tilde{\epsilon}(q)|) + \left| V(k - q) \right|^2 + \frac{1}{4} \left| t(q) \right|^2 \chi_{sf}(k - q) \theta(\omega_c - |\tilde{\epsilon}(q)|) \right\}, \tag{78}
\]
where \(\theta\)-functions restrict the integration over \(q\) for \(|\tilde{\epsilon}(q)| < \Omega\). To compare contributions for pairing from the spin fluctuations and the EPI we take into account in the interaction \(|g_{sf}(k, q)|^2\) only the first term \(|t(q)|^2\).

Solution of the gap equation (78) in the WCA, \(Z(q) = 1\), for \(T_c\) as a function of doping is presented in Fig. 20. Solution of the gap equation (78) for \(T_c\) in the SCA for \(Z(q)\) given in Fig. 19 is shown in Fig. 21. To simplify the numerical calculation we approximated the function \(Z(q)\) by its average over \(q\) values: \(Z = 2.1, 1.7, 1.3\) for \(\delta = 0.1, 0.2, 0.3\), respectively, which can be described by the function \(Z = 2.5 - 4\delta\). The superconducting \(T_c\) in the SCA in Fig. 21 is an order of magnitude smaller than in the WCA in Fig. 20 due to suppression of the QP weight given by \(1/Z(q)\).

To emphasize existences of two channels of pairing in our theory, induced by the unretarded interaction \(J\) and the retarded spin-fluctuation interaction, we include in Figs. 20 and 21 the results for \(T_c\) without CI \(V\) (dotted green line). In this case there is no suppression of the interaction \(J\) by \(CI V\), as in the GMFA in Fig. 4 and both contributions to \(T_c\) are revealed. We see that the interaction \(J\) considerably enhance \(T_c\) but the main contribution comes from the retarded EPI and interaction with spin-fluctuations. A more detailed discussion of the role of CI \(V\) was given for the Hubbard model in Ref. 124. It was shown that spin-fluctuations is a separate channel of pairing, which can be suppressed only for \(CI V \gtrsim 3t\), much larger than the exchange interaction \(J \leq 0.4t\). The same result holds for the \(t - J - V\) model not presented in the manuscript for shortness reason. Existence of two components of pairing interaction induced by the nonretarded exchange interaction \(J\) and retarded spin-fluctuation interaction in the Hubbard and
$t$–$J$ models was discussed in Ref. [141]. It was concluded that the basis is the retarded spin-fluctuation interaction which can be considered as a “glue” which mediates the $d$-wave pairing. This conclusion was confirmed in ARPES experiments, see, e.g., Ref. [142].

The role of intersite CI is also discussed in Ref. [143]. Using the variational Monte Carlo technique the superconducting $d$-wave gap was calculated for the extended Hubbard model with a weak exchange interaction $J = 0.2t$ and a repulsion $V \leq 3t$ in a broad range of $0 \leq U \leq 32$. It was found that the gap decreases with increasing $V$ at all $U$ and can be suppressed for $V > J$ for small $U$. But for large $U \gtrsim U_c \sim 6t$ the gap becomes robust and exists up to large values of $V \sim 10J = 2t$. At the same time, the gap does not show notable variation with $U$ for large $U = 10 - 30$ though it should depend on the conventional exchange interaction in the Hubbard model $J = 4t^2/U$. We can explain these results by pointing out that at large $U \gtrsim U_c$ concomitant decrease of the bandwidth in Ref. [142] results in the splitting of the Hubbard band into the upper and lower subbands and emerging the kinematic interaction which induces the $d$-wave pairing in one Hubbard subband. In that case the second subband for large $U$ gives a small contribution which results in $U$-independent pairing. It can be suppressed by the repulsion $V$ only larger than the kinematic interaction, $V \gtrsim 2t$.

We calculated also $T_c$ for several next-nearest-neighbor parameters $t'$. It was found that $T_c^{\text{max}}$ increases with increasing of $t'$ as was found also in Ref. [98]. Variation of $t'$ results in changing of the FS but it also changes the spin-fluctuation interaction $|t(q)|^2$. For the FS close to the AFM BZ, $X(\pi,0) \rightarrow Y(0,\pi)$, $(\cos k_x + \cos k_y = 0)$, the interaction given by the hopping parameter $2t(\cos k_x + \cos k_y)$ is weak while the interaction determined by the hopping parameter $t'\cos k_x \cos k_y$ gives a substantial contribution to the $d$-wave symmetry order parameter $\phi_d(q) \propto \cos k_x - \cos k_y$. Increasing of $T_c^{\text{max}}$ with $t'$ was found in the band-structure calculations [144] and observed in ARPES experiments [145].

Comparison of $T_c$ in the WCA in Fig. 20 and in the SCA in Fig. 21 shows that in both approximations the contribution from the EPI is noticeably smaller than those induced by the spin-fluctuation interaction. To explain this we note a difference between the self-energy for the normal state [68] and in the gap equation [74]. While in summation over $q$ contributions to the normal self-energy come from all symmetry components of interactions, in the gap equation contributions are restricted only to the $B_{1g}$ symmetry component of interactions determined by the symmetry of the $d$-wave gap $\phi_d(q)$. In particular, a strong momentum-independent EPI gives no contribution to the gap equation but results in a large contribution to the normal self-energy and the parameter $Z(q)$ in the gap equation that suppresses $T_c$ (see also Ref. [132]). Therefore, the EPI can be quite strong and gives observable polaronic effects but has a small $d$-wave partial harmonic and plays only a secondary role in the

d-wave pairing. This results in the weak isotope effect on $T_c$ in the optimally doped cuprates. The same holds for the intersite CI since only $d$-wave partial harmonic gives a contribution to the gap equation. The wave-vector dependence of the superconducting gap at the FS $\phi(q)$ at $\delta = 0.2$ is presented in Fig. 22 in the BZ. The angle dependence $\phi(\theta)$ is shown in Fig. 23 where the angle $\theta$ is measured from the direction $M(\pi,\pi) \rightarrow X(\pi,0)$ to the direction $M(\pi,\pi) \rightarrow Y(0,\pi)$. We see that the maximum values of the gap are shifted in comparison with the model $d$-wave gap function $\phi(q) = \phi_J(\cos k_x - \cos k_y)$ from the BZ boundary at $(0,\pm\pi), (\pm\pi,0)$ points. Similar behavior was found in Ref. [57] in the $t$–$J^*$ model with hopping parameters between distant lattice sites.

\section{VI. SUMMARY}

A detailed study of the electronic spectrum and superconductivity for strongly correlated electronic systems within the microscopic theory for the extended $t$–$J$ model [1] is presented. Besides the conventional AFM exchange interaction $J$, the EPI and the intersite Coulomb repulsion are taken into account [2]. The projection technique was employed to obtain the exact Dyson equation for the normal and anomalous (pair) GFs [21] in terms of the Hubbard operators. The self-energy [22] given by many-particle GFs was calculated in
the SCBA (50, 51) in the second order of interactions. The most important contribution is induced by the kinematical interaction for the Hubbard operators (3). It results in a strong coupling of the electrons with spin fluctuations of the order of hopping parameter \( t(q) \) much larger than the exchange interaction \( J(q) \). Vertex corrections to this interaction in the SCBA should be small, of the order of \( \omega_k/\mu \), the spin-fluctuation energy \( \omega_k \), to the Fermi energy \( \mu \), as is in the Eliashberg theory of EPI (120) with a small parameter \( \omega_{ph}/\mu \) where \( \omega_{ph} \) is a phonon energy.

In the generalized MFA, the first order of the projection technique, the electronic spectrum in Fig. 1 describes well-defined QP excitations. The FS in Fig. 2 shows a transformation from the four-pocket shape in the BZ at small doping to a large FS for higher doping. The superconducting \( T_c \) induced by the exchange interaction \( J \) in the MFA in Fig. 4 is large as in the RVB theory of Anderson (6) commonly used in many publications. However, the intersite Coulomb repulsion strongly reduces the exchange interaction pairing and brings to a location \( T_c \).

The self-energy contributions result in a strong renormalization both the electronic spectrum and superconductivity. The spectral density and the electron dispersion, Figs. 5 - 10 reveal damped excitations with the FS in the form of arcs at low doping, Figs. 14, 15. The same strong coupling of electrons with spin fluctuations results in high-\( T_c \) for the \( d \)-wave pairing. The EPI and the intersite Coulomb repulsion play a minor role for the \( d \)-wave pairing since they are determined only by the \( d \)-wave partial harmonic in the gap equation. But the quasiparticle weight renormalization due to the normal state self-energy gives an order of magnitude smaller than the SCBA (50, 51) in the second order of interactions.

After summation over \( \sigma' \) in (80) for the normal GF in the paramagnetic state, \( G_{\uparrow \downarrow \sigma}(\omega) = G_{\downarrow \uparrow \sigma}(\omega) \), the spin-fluctuation contribution to the bosonic GF (81) takes the form: \( \langle S_i^\sigma | S_j^\sigma \rangle \omega + \langle X_i^{\sigma} | X_j^{\sigma} \rangle \omega = \langle (S_i | S_j) \rangle \omega \). Introducing the Fourier representation similar to (12) we obtain for the spin-fluctuation contribution to the self-energy

\[
M_{ij}^{sf}(\omega) = \int \frac{dzd\Omega}{2\pi^2} \frac{\tanh(z/2T) + \coth(\Omega/2T)}{\omega - z - \Omega} \times \sum_{l^\prime} t_{il^l} t_{l^l j} \operatorname{Im} G_{\uparrow \downarrow \sigma}(\omega) \operatorname{Im} \langle B_{i\sigma\sigma'} | B_{j\sigma\sigma'} \rangle \omega.
\]

After summation over \( \sigma' \) in (80) for the normal GF in the paramagnetic state, \( G_{\uparrow \downarrow \sigma}(\omega) = G_{\downarrow \uparrow \sigma}(\omega) \), the spin-fluctuation contribution to the bosonic GF (81) takes the form: \( \langle S_i^\sigma | S_j^\sigma \rangle \omega + \langle X_i^{\sigma} | X_j^{\sigma} \rangle \omega = \langle (S_i | S_j) \rangle \omega \). Introducing the Fourier representation similar to (12) we obtain for the spin-fluctuation contribution to the self-energy

\[
M_{ij}^{sf}(\omega) = \int \frac{dzd\Omega}{2\pi^2} \frac{\tanh(z/2T) + \coth(\Omega/2T)}{\omega - z - \Omega} \times \sum_{l^l} g_{il} g_{l^l j} \operatorname{Im} G_{\uparrow \downarrow \sigma}(\omega) \operatorname{Im} \langle N_i | N_j^{\dagger} \rangle \omega.
\]

Calculations for the CI and the EPI give the corresponding contribution to the self-energy (83):

\[
M_{ij}^{CI \text{EPI}}(\omega) = \int \frac{dzd\Omega}{2\pi^2} \frac{\tanh(z/2T) + \coth(\Omega/2T)}{\omega - z - \Omega} \times \left\{ \sum_{l^l} V(i, l) V^*(i, l) \operatorname{Im} G_{i\sigma}(\omega) \operatorname{Im} \langle N_i | N_i^{\dagger} \rangle \omega \right. \\
+ \left. \sum_{l^l} g_{il} g_{l^l j} \operatorname{Im} G_{\uparrow \downarrow \sigma}(\omega) \operatorname{Im} \langle N_i | N_j^{\dagger} \rangle \omega \right\}
\]

As a result, after the Fourier transformation of all the contributions in equation (83) we obtain the normal self-energy given by Eq. (52).

VII. APPENDIX

To calculate the many-particle GFs in the self-energy (45, 49) we introduce the time-dependent correlation function using the spectral representation, as, e.g.,

\[
\langle B_{i\sigma\sigma'} | X_{i\sigma'}^{0} | B_{j\sigma\sigma'} \rangle \omega = \int_{-\infty}^{\infty} \frac{dz}{2\pi^2} e^{i \omega T} + \frac{1}{\omega - z} \times \int_{-\infty}^{\infty} dt e^{i z t} \langle X_{i\sigma'}^{0} | B_{j\sigma\sigma'}(t) X_{i\sigma'}^{0} \rangle (t),
\]
Similar calculations for the many-particle anomalous component of the self-energy result in the equation

$$\Phi_{ij\sigma}(\omega) = \frac{1}{Q} \sum_{l,l'} \left\{ \sum_{\sigma} t_{il} t_{j'l'} \langle B_{i\sigma\sigma} | X^{0\sigma'}_{l'} | B_{j\bar{\sigma}\bar{\sigma}} X^{0\bar{\sigma}'}_{l} \rangle \right\}_{\omega}$$

$$- V(i,l)V(j,l') \langle X^{0\sigma}_l N^0_j | X^{0\bar{\sigma}}_l N^0_j \rangle$$

$$- g_{ll'} \langle X^{0\sigma}_l u_l | X^{0\bar{\sigma}}_{l'} u_{l'} \rangle \right\}_{\omega}.$$  \hspace{1cm} (84)

For the many-particle anomalous GF we have

$$\langle B_{i\sigma\sigma} | X^{0\sigma'}_{l'} | B_{j\bar{\sigma}\bar{\sigma}} X^{0\bar{\sigma}'}_{l} \rangle = \frac{1}{2\pi} \int_{-\infty}^{\infty} dz \frac{e^{z/T} + 1}{\omega - z}$$

$$\times \int_{-\infty}^{\infty} dt e^{i\omega t} \langle X^{0\sigma'}_{l'} B_{j\bar{\sigma}\bar{\sigma}}(t) X^{0\bar{\sigma}'}(t) \rangle.$$  \hspace{1cm} (85)

Then using the SCBA \textbf{[61]} we calculate the time-dependent correlation functions self-consistently using the corresponding anomalous GFs. Integration over time \( t \) in Eq. (85) yields for the anomalous self-energy:

$$\Phi_{ij\sigma}(\omega) = \int \int_{-\infty}^{\infty} \frac{dz d\Omega}{2\pi^2 Q} \frac{\tanh(z/2T) + \coth(\Omega/2T)}{\omega - z - \Omega}$$

$$\times \sum_{l,l'} \left\{ \sum_{\sigma'} t_{il} t_{j'l'} \text{Im} \langle X^{0\sigma'}_{l'} X^{0\bar{\sigma}'}_{l} \rangle \text{Im} \langle B_{i\sigma\sigma} | B_{j\bar{\sigma}\bar{\sigma}} \rangle \right\}_{\omega}$$

$$- \text{Im} \langle X^{0\sigma}_l | X^{0\bar{\sigma}}_l \rangle \text{Im} \langle | N^0_l | N^0_l \rangle \Omega$$

$$- \text{Im} \langle X^{0\sigma}_l | X^{0\bar{\sigma}}_l \rangle \text{Im} \langle | u_l | u_l \rangle \Omega\}.$$  \hspace{1cm} (86)

Here for the bosonic GF we have the relation

$$\langle B_{i\sigma\sigma} | B_{j\bar{\sigma}\bar{\sigma}} \rangle_{\omega} = (1/4) \langle N^0_l N^0_l \rangle \delta_{\sigma\sigma}$$

$$- \langle S^z_i | S^z_j \rangle \delta_{\sigma\sigma} + \langle X^{0\sigma}_l | X^{0\bar{\sigma}}_l \rangle \omega \delta_{\sigma\bar{\sigma}}.$$  \hspace{1cm} (87)

Summation over \( \sigma' \) for the bosonic GF \textbf{[77]} and the anomalous GF \( F_{i\sigma}(\omega) = -F_{i\bar{\sigma}}(\omega) \) in Eq. \textbf{[86]} results in the relation: \(-\langle S^z_i | S^z_j \rangle \omega F_{i\sigma}(\omega) = -\langle S^z_i | S^z_j \rangle \omega F_{i\bar{\sigma}}(\omega) \) After the Fourier transformation of all the contributions in \textbf{[86]} we obtain the anomalous self-energy component \textbf{[82]}.
