Frequency shift of cesium clock transition due to blackbody radiation

E. J. Angstmann, V. A. Dzuba, and V. V. Flambaum
School of Physics, University of New South Wales, Sydney 2052, Australia
(Dated: February 3, 2022)

We have performed ab initio calculations of the frequency shift induced by a static electric field on the cesium clock hyperfine transition. The calculations are used to find the frequency shifts due to blackbody radiation. Our result \( \delta \nu/E^2 = -2.26(2) \times 10^{-23}\text{Hz}/(\text{V/m})^2 \) is in good agreement with early measurements and ab initio calculations performed in other groups. We present arguments against recent claims that the actual value of the effect might be smaller. The difference \( \sim 10\% \) between ab initio and semiempirical calculations is due to the contribution of the continuum spectrum to the sum over intermediate states.

PACS numbers: 32.60.+i,31.30.Gs,31.25.Eb

Atomic clocks are now important for both practical applications and fundamental physics. One of the dominant uncertainties in high-precision measurements of frequencies in atomic clocks is the ac stark shift induced by blackbody radiation (see e.g. [1]). There is some disagreement on the value of this shift. Early measurements [2, 4, 7] and ab initio calculations [3, 9, 12] support a value which is close to \(-2.2 \times 10^{-10}\text{Hz}/(\text{V/m})^2\) while more recent measurements [10, 11] and semiempirical calculations [3, 9, 12] claim that actual number might be about 10% smaller.

In the present work we have performed fully ab initio calculations of the radiation frequency shift and have identified the source of the disagreement between different theoretical results as the contribution of the continuum spectrum states into summation over the complete set of intermediate states. The continuum spectrum was included in all the ab initio calculations and missed in the semiempirical considerations. We demonstrate that adding the contribution of the continuum spectrum to where it was missed brings all theoretical results to good agreement with each other and with early measurements.

Blackbody radiation creates a temperature dependent electric field, described by the Planck radiation law

\[
E^2(\omega) = \frac{8\alpha}{\pi} \frac{\omega^3 d\omega}{\exp(\omega/kT) - 1}. \tag{1}
\]

This leads to the following expression for the average electric field radiated by a black body at temperature \( T \):

\[
\langle E^2 \rangle = (831.9\text{V/m})^2[T(\text{K})/300]^4. \tag{2}
\]

This electric field causes a temperature-dependent frequency shift of the atomic microwave clock transitions. It can be presented in the form (see, e.g. [1])

\[
\frac{\delta \nu}{\nu_0} = \beta (T/T_0)^4 \left[ 1 + \epsilon(T/T_0)^2 \right] \tag{3}
\]

Here \( T_0 \) is usually assumed to be room temperature (\( T_0 = 300K \)). The frequency shift in a static electric field is

\[
\delta \nu = k E^2. \tag{4}
\]

Coefficients \( k \) and \( \beta \) are related by

\[
\beta = \frac{k}{\nu_0^2} (831.9\text{V/m})^2
= k \times 7.529 \times 10^{-5}(\text{V/m})^2\text{Hz}^{-1} \text{ (for Cs)},
\]

while \( \epsilon \) is a small correction due to frequency distribution [1]. In the present work we calculate the coefficient \( k \).

In the case when there is no other external electric field the radiation shift can be expressed in terms of the scalar hyperfine polarizability of the atom. This corresponds to averaging over all possible directions of the electric field. The hyperfine polarizability is the difference in the atomic polarizabilities between different hyperfine structure states of the atom. The lowest-order effect is linear in the hyperfine interaction and quadratic in the electric field. The corresponding third-order perturbation theory expressions, after angular reduction have the form

\[
\delta \nu_1(\text{as}) = e^2 \langle E^2 \rangle \frac{2I+1}{6} \times \\
\sum_{n,m,j} \frac{A_{\text{as},\text{ns}} \langle ns || mp_j \rangle \langle mp_j || r || \text{as} \rangle}{(\epsilon_{\text{as}} - \epsilon_{\text{ns}})(\epsilon_{\text{as}} - \epsilon_{mp_j})}, \tag{6}
\]

\[
\delta \nu_2(\text{as}) = e^2 \langle E^2 \rangle \frac{2I+1}{6} \sum_j (C_{I+1/2} - C_{I-1/2}) \times \\
\sum_{n,m} \frac{\langle as || r || np_j \rangle A_{\text{np},\text{mp}} \langle mp_j || r || \text{as} \rangle}{(\epsilon_{\text{as}} - \epsilon_{np_j})(\epsilon_{\text{as}} - \epsilon_{mp_j})}, \tag{7}
\]

and

\[
\delta \nu_{\text{norm}}(\text{as}) = \\
- e^2 \langle E^2 \rangle \frac{2I+1}{12} A_{\text{as}} \sum_{m,j} \frac{|\langle as || r || mp_j \rangle|^2}{(\epsilon_{\text{as}} - \epsilon_{mp_j})^2}. \tag{8}
\]

Here

\[
C_F = \sum_{F'} (2F'+1) |F'(F'+1) - I(I+1) - j(j+1)| \\
\times \left\{ \begin{array}{c}
1/2 \ F' \\
F' \\
1 \end{array} \right\}^2, \quad F' = |I - J|, I + J,
\]

and

\[
A_{\text{as}} = \sum_{m,j} \frac{\langle as || r || np_j \rangle A_{\text{np},\text{mp}} \langle mp_j || r || \text{as} \rangle}{(\epsilon_{\text{as}} - \epsilon_{np_j})(\epsilon_{\text{as}} - \epsilon_{mp_j})}
\]
$A_{ns}$ is the hfs constant of the $ns$ state, $A_{m,n}$ is the off-
diagonal hfs matrix element, $I$ is nuclear spin, $F = I + J$, $J$ is total electron momentum of the atom in the ground
state ($J = 1/2$), and $j$ is total momentum of virtual $p$-
states ($j = 1/2, 3/2$). Summation goes over a complete
set of $ns$, $mp_{1/2}$ and $mp_{3/2}$ states.

In order to calculate frequency shift to the hfs transitions
due to the electric field one needs to have a complete
set of states and to have the energies, electric dipole
transition amplitudes and hyperfine structure matrix ele-
ments corresponding to these states. It is possible to
consider summation over the physical states and to then
use experimental data to perform the calculations. The
lowest valence states for which experimental data is usu-
ally available dominate in the summation. Off-diagonal
hfs matrix elements can be obtained to a high accuracy
as the square root of the product of corresponding hfs
constants: $A_{m,n} = \sqrt{A_m A_n}$ (see, e.g. 18). However,
the accuracy of this approach is limited by the need to
include the tail contribution from highly excited states
including states in the continuum. This contribution can
be very significant and its calculation is not easier than
the calculation of the whole sum.

Therefore, in the present work we use an ab initio ap-
proach in which high accuracy is achieved by the inclu-
sion of all important many-body and relativistic effects.
We make only one exception toward the semiempirical
approach. The frequency shift is dominated by the term
which is proportional to the hfs in the ground state.
It is natural to use experimental hfs constant in the domi-
nating term to have more accurate results. Note however
that the difference with complete ab initio calculations is
small.

Calculations start from the relativistic Hartree-Fock
(RHF) method in the $V^{N-1}$ approximation. This means
that the initial RHF procedure is done for a closed-shell
atomic core with the valence electron removed. After
that, states of the external electron are calculated in the
field of the frozen core. Correlations are included by
means of the correlation potential method 16. We use
two different approximations for the correlation poten-
tial, $\Sigma_i$. First, we calculate it in the lowest, second-order
of the many-body perturbation theory (MBPT). We use
notation $\Sigma^{(2)}$ for the corresponding correlation poten-
tial. Then we also include into $\Sigma$ two classes of the higher-
order terms: screening of the Coulomb interaction and
hole-particle interaction (see, e.g. 17 for details). These
two effects are included in all orders of the MBPT and
the corresponding correlation potential is named $\Sigma^{(\infty)}$.

To calculate $\Sigma^{(2)}$ we need a complete set of single-
electron orbitals. We use the B-spline technique 18, 19
to construct the basis. The orbitals are built as linear
combinations of 50 B-splines in a cavity of radius 40 $a_0$.
The coefficients are chosen from the condition that the
orbitals are eigenstates of the RHF Hamiltonian $\hat{H}_0$ of the
closed-shell core. The $\Sigma^{(\infty)}$ operator is calculated with
the technique which combines solving equations for the
Green functions (for the direct diagram) with the summa-
tion over complete set of states (exchange diagram) 17.

The correlation potential $\Sigma$ is then used to build a new
set of single-electron states, the so-called Brueckner or-
itbals. This set is to be used in the summation in equa-
tions (8), (7) and (6). Here again we use the B-spline
 technique to build the basis. The procedure is very simi-
lar to the construction of the RHF B-spline basis. The
only difference is that new orbitals are now the eigen-
states of the $\hat{H}_0 + \Sigma$ Hamiltonian, where $\Sigma$ is either $\Sigma^{(2)}$
or $\Sigma^{(\infty)}$.

Brueckner orbitals which correspond to the lowest va-
lence states are good approximations to the real physical states.
Their quality can be checked by comparing experi-
mental and theoretical energies. Moreover, their quality
can be further improved by rescaling the correlation po-
tential $\Sigma$ to fit experimental energies exactly. We do this
by replacing the $\hat{H}_0 + \Sigma$ with the $\hat{H}_0 + \lambda \Sigma$ Hamiltonian in
which the rescaling parameter $\lambda$ is chosen for each partial
wave to fit the energy of the first valence state. The values
of $\lambda$ are $\lambda_s = 0.8$ and $\lambda_p = 0.85$ for $\Sigma^{(2)}$ and $\lambda_s = 0.99$
and $\lambda_p = 0.95$ for $\Sigma^{(\infty)}$. Note that the values are very
close to unity. This means that even without rescaling
the accuracy is very good and only a small adjustment to
the value of $\Sigma$ is needed. Note also that since the rescal-
ing procedure affects both energies and wave functions, it
usually leads to improved values of the matrix elements
of external fields. In fact, this is a semiempirical method
to include omitted higher-order correlation corrections.

Matrix elements of the hfs and electric dipole opera-
tors are found by means of the time-dependent Hartree-
Fock (TDHF) method 16, 22. This method is equivalent
to the well-known random-phase approximation (RPA).
In the TDHF method, single-electron wave functions are
presented in the form $\psi = \psi_0 + \delta \psi$, where $\psi_0$ is unper-
turbed wave function. It is an eigenstate of the RHF
Hamiltonian $\hat{H}_0$: $(\hat{H}_0 - \epsilon) \psi_0 = 0$. $\delta \psi$ is the cor-
rection due to external field. It can be found by solving the
TDHF equation

$$(\hat{H}_0 - \epsilon) \delta \psi = -\delta \epsilon \psi_0 - \hat{F} \psi_0 - \delta \hat{V}^{N-1} \psi_0,$$

where $\delta \epsilon$ is the correction to the energy due to external
field ($\delta \epsilon \equiv 0$ for the electric dipole operator), $\hat{F}$ is the op-
erator of the external field ($\hat{H}_i$, or $e \mathbf{E} \cdot \mathbf{r}$), and $\delta \hat{V}^{N-1}$ is
the correction to the self-consistent potential of the core
due to external field. The TDHF equations are solved
self-consistently for all states in the core. Then matrix ele-
ments between any (core or valence) states $n$ and $m$ are given by

$$(\psi_n | \hat{F} + \delta \hat{V}^{N-1} | \psi_m).$$

The best results are achieved when $\psi_n$ and $\psi_m$ are
Brueckner orbitals calculated with rescaled correlation
potential $\Sigma$.

We use equation 18, for all hfs and electric dipole
matrix elements in (6), (7), and (5) except for the ground
state hfs matrix element in (5) where we use experimental
data.
To check the accuracy of the calculations we perform calculations of the hfs in the ground state and of the static scalar polarizability. Polarizability is given by the expression

\[ a_0(a) = \frac{2}{3} \sum_{m} \frac{|a||r||m|^2}{\epsilon_n - \epsilon_m} \]

(11)

which is very similar to the term \( \hat{\Sigma} \) for the frequency shift. The most important difference is that the energy denominator is squared in term \( \hat{\Sigma} \) but not in \( a_0 \). This means better convergence with respect to the summation over complete set of states for term \( \hat{\Sigma} \) than for \( a_0 \). Therefore, if good accuracy is achieved for polarizabilities, even better accuracy should be expected for the term \( \hat{\Sigma} \) (see also Ref. [9]).

However, the behavior of the other two terms, \( \hat{\Sigma} \) and \( \hat{\Sigma} \), is very different and calculation of polarizabilities tells us little about accuracy for these terms. Therefore, we also perform detailed calculations of the hfs constants of the ground state. Inclusion of core polarization (second term in \( \hat{\Sigma} \)) involves summation over the complete set of states similar to what is needed for term \( \hat{\Sigma} \). Comparing experimental and theoretical hfs is a good test for the accuracy for this term.

In addition to term \( \hat{\Sigma} \), we also include two smaller contributions to the hfs: structure radiation and the correction due to the change of the normalization of the wave function. Our final result for the hfs constant is 2298 MHz which is in excellent agreement with the experimental value 2298 MHz [22]. The result for static polarizability is \( a_0 = 399.0 a_0^3 \) which is also in a very good agreement with experimental value 401.0(6) \( a_0^3 \) [14].

Table I presents contributions of terms \( \hat{\Sigma} \), \( \hat{\Sigma} \) and \( \hat{\Sigma} \) into the total frequency shift of the hfs transition for the ground state of \( ^{133}\text{Cs} \) calculated in different approximations. Term \( \hat{\Sigma} \) dominates while term \( \hat{\Sigma} \) is small but still important. Results obtained with \( \hat{\Sigma} \) and \( \hat{\Sigma} \) differ significantly (14%). However, after rescaling the results for both \( \hat{\Sigma} \) and \( \hat{\Sigma} \) come within a fraction of a per cent of each other. Naturally, rescaling has a larger effect on results obtained with \( \hat{\Sigma} \). This means that the rescaling really imitates the effect of higher-order correlations and should lead to more accurate results.

In summary, we have three ways of estimation of the accuracy of calculations: (a) calculation of static polarizability (0.5% accuracy); (b) calculation of the hfs (0.9% accuracy); and (c) comparison of the results obtained in different most accurate approximations (three last lines of Table I), which differ by about 0.3%. Therefore, we can say that the accuracy of the calculations is not worse that 1%. Our final result is

\[ k = -2.26(2) \times 10^{-10}\text{Hz}/(\text{V/m})^2. \]

(12)

This corresponds to \( \beta = -1.70(2) \times 10^{-14} \). To obtain frequency shift at finite temperature one needs to substitute this value into equation (11). For accurate results one also needs to know the value of \( \epsilon \). It was estimated in Ref. [1] in single-resonance approximation and found to be 0.014. In many-resonance calculation \( \epsilon \) will be 10-20% smaller.

We present our final result for the frequency shift together with other theoretical and experimental results in Table II. Our value is in good agreement with early measurements [2, 4, 7] and \( \text{ab initio} \) calculations [3, 8] while recent measurements [10, 11] and semiempirical calculations [3, 8, 12] give the value which is about 10% smaller. Less accurate measurements of Bauch and Schröder [6] cover both cases. We cannot comment on disagreement between experimental results. However, the source of disagreement between theoretical results seems to be clear. It comes from the contribution of the continuum spectrum to the summation over the complete set of states in term \( \hat{\Sigma} \). This term has off-diagonal hfs matrix elements between the ground state and excited states. Since the hfs interaction is localized over short distances (~ \( a_0/Z \)) it emphasizes the contribution of states with high energies including states in the continuum (since \( \Delta \nu \Delta x \gtrsim \hbar \), a small area of localization (\( \Delta x \)) allows high momentum (\( \mu \) and thus high energy). In our calculations the contribution of the states above \( 7p \) into term \( \hat{\Sigma} \) is \(-0.35 \times 10^{-10}\text{Hz}/(\text{V/m})^2 \) which is 15% of the total answer.

In contrast, states above \( 7p \) contribute only about 0.05% of the total value of term \( \hat{\Sigma} \). This is because the summation goes over the matrix elements of the electric dipole operator which is large on large distances and thus suppresses the contribution of high-energy states. It is not surprising therefore that a semiempirical consideration, involving only discrete spectrum states, gives very good results for the atomic polarizabilities (see, e.g. [8]). However, let us stress once more that the calculation of polarizabilities checks only term \( \hat{\Sigma} \) and tells us very little about the accuracy of other two terms, \( \hat{\Sigma} \) and \( \hat{\Sigma} \).

The contribution of the states above \( 7p \) is even more important for term \( \hat{\Sigma} \). Their contribution is about 30% of the total value of this term. However, the term itself is small and its accurate treatment is less important.

In \( \text{ab initio} \) calculations by Lee et al. [5] summation over complete set of states is reduced to solving of a radial equation (equations of this type are often called Stern-
TABLE II: Electrostatic frequency shifts for the hyperfine transition of Cs ($\delta \nu_0/E^2 \times 10^{-10}$ Hz/(V/m)^2); comparison with other calculations and measurements.

| This work | Other calculations | Ref Measurements | Ref |
|-----------|--------------------|------------------|-----|
| -2.26(2)  | -1.9(2)            | [3] -2.29(7)     | [2] |
| -2.2302   | -2.25(5)           | [5] -2.25(5)     | [4] |
| -2.28     | -2.17(26)          | [8] -2.17(26)    | [6] |
| -1.97(9)  | -2.271(4)          | [9] -2.17(26)    | [7] |
| -2.06(1)  | -1.89(12)          | [10] -1.89(12)   |     |
| -2.268(8) | -2.03(4)           | [11] -2.03(4)    |     |

The approach does include the contribution of the continuum spectrum and the result is in very good agreement with ours (see Table II).

In other \textit{ab initio} calculations by Pal’chikov \textit{et al} [8] summation is done via Green functions. This corresponds to summation over the complete set of states and does include the continuum spectrum. Again, the result is in very good agreement with other \textit{ab initio} calculations ([2] and the present work).

Recent calculations by Beloy \textit{et al} [13] applied a mixed approach, with extensive use of experimental data for lower cesium states and \textit{ab initio} summation over higher states including continuum. The result is in good agreement with fully \textit{ab initio} calculations.

In contrast, analysis performed in [3, 9, 12] is limited to discrete spectrum. Adding $-0.34 \times 10^{-11}$ Hz/(V/m)^2 (which is total tail contribution from all three terms [6], [7] and [8] found in our calculation) to the results of Feitchner \textit{et al} [3] and Micalizio \textit{et al} [9] brings them to excellent agreement with \textit{ab initio} calculations. The same modification of the result by Ulzega \textit{et al} [12] makes it a little bit too large but still closer to other results than without the tail contribution.

We are grateful to S. Ulzega, W. Itano, and A. Derevianko for useful comments and references.
