Coagulation by Random Velocity Fields as a Kramers Problem

Bernhard Mehlig$^1$ and Michael Wilkinson$^2$

We analyse the motion of a system of particles suspended in a fluid which has a random velocity field. There are coagulating and non-coagulating phases. We show that the phase transition is related to a Kramers problem, and use this to determine the phase diagram, as a function of the dimensionless inertia of the particles, $\epsilon$, and a measure of the relative intensities of potential and solenoidal components of the velocity field, $\Gamma$. We find that the phase line is described by a function which is non-analytic at $\epsilon = 0$, and which is related to escape over a barrier in the Kramers problem. We discuss the physical realisations of this phase transition.

Deutsch$^1$ introduced and investigated a model which can describe the motion of particles suspended in a randomly moving fluid. He showed that the one-dimensional model exhibits a phase transition between coagulating and non-coagulating phases as the effect of inertia of the particles is increased. We recently solved Deutsch's one-dimensional model exactly ("path-coalescence model"$^2$).

This letter discusses the phase diagram for the path-coalescence model in higher dimensions, which is the most relevant case for physical applications. In the limit where inertial effects are negligible, the suspended particles are advected by the flow: the theory of this limiting case is described in$^3$. The case where the inertia of the particles play an important role is much less thoroughly understood. In Ref. $^4$ a model is described in which the aggregation of buoyant particles on the surface of a turbulent liquid has also been studied$^5$. Here we give a treatment of the phase transition in higher dimensions, using an exact mapping to a Kramers problem

In the following we discuss the phase transition in two dimensions (Fig. 1). The three-dimensional case is considerably harder to analyse, but the results are surprisingly similar. We derive a perturbation expansion for a Liapunov exponent $\lambda_1$ determining the phase transition, in powers of a dimensionless measure of the inertia, $\epsilon$. Surprisingly, the perturbative result for the phase line turns out to be independent of $\epsilon$. Our numerical simulations, by contrast, imply that the phase line does depend upon $\epsilon$. We resolve this apparent inconsistency by showing that there is a contribution $\delta \lambda_1$ to $\lambda_1$ which is non-analytic in $\epsilon$, characteristic of the flux over a barrier in a Kramers problem: $\delta \lambda_1 \sim \exp(-\Phi/\epsilon^2)$, where $\Phi$ is the action of a trajectory in a Hamiltonian dynamical system. We conclude with a discussion of physical applications.

We consider non-interacting spherical particles of mass $m$, radius $a$, and $r(t)$ denotes the position of a typical particle. These move through a fluid with velocity $u(r,t)$ having viscosity $\eta$. To avoid complications from displaced-mass effects$^6$, we assume that the particles have much higher density than the surrounding fluid. Our results are therefore most relevant to suspensions in gases, and we allow $u(r,t)$ to be a compressible flow (by contrast, Refs. $^4$ $^5$ treat the case relevant to suspensions in liquids). We consider the case where the drag force $f_d$ on the particle is given by Stokes' law: $f_d = 6\pi\eta a (u - \dot{r})$. The equation of motion is

$$\dot{r} = -\gamma (\dot{r} - u)$$

where $\gamma = 6\pi\eta a/m$. Rearranging (1) gives $\dot{r} = p/m$, $\dot{p} = -\gamma p + f(r,t)$ where $f = \gamma ma$ will be modelled by a random field. Linearising to obtain an equation for the separation $(\delta r, \delta p)$ of two nearby trajectories gives

$$\dot{\delta r} = \delta p/m, \quad \dot{\delta p} = -\gamma \delta p + F(t)\delta r$$

(2) where $F(t)$ is a $2 \times 2$ matrix with elements $F_{ij}(t) = \partial f_i/\partial r_j(r(t),t)$. We write $\delta r = X\delta \theta$ and $\delta p = Y_1 X\delta \theta + Y_2 X\delta \theta + \gamma/2$, where $\delta \theta$ is unit vector in direction $\theta$. We expect that the scale variable $X$ may increase or decrease, but that $\theta$, $Y_1$, and $Y_2$ approach a stationary distribution.

The phase transition is determined by the behaviour of $X$: if the (maximal) Liapunov exponent $\lambda_1 =$
$m^{-1}d\log X/dt$ is negative, the particles coagulate. Substituting the expressions for $\dot{\theta}$ and $\dot{\phi}$ into (2), and taking scalar products with $\hat{n}_\theta$ and $\hat{n}_{\theta+\pi/2}$ we obtain

$$\dot{X} = Y_1 X/m, \quad \dot{\theta} = Y_2/m$$

and

$$\dot{Y}_1 = (Y_2^2 - Y_1^2)/m - \gamma Y_1 + F_3(t)$$

$$\dot{Y}_2 = -2Y_1Y_2/m - \gamma Y_2 + F_0(t)$$

where $F_3(t) = \hat{n}_\theta F(t)\hat{n}_\theta$ and $F_0(t) = \hat{n}_{\theta+\pi/2} F(t)\hat{n}_\theta$. From (3), the distribution of $\theta$ becomes uniform on $[0, 2\pi]$ at large $t$, and the Liapunov exponent is

$$\lambda_1 = \langle Y_1 \rangle / m.$$  

The statistics of the random force is assumed to be rotationally invariant, so that the statistics of $F_3$ and $F_0$ are independent of $\theta$. For $\theta = 0$, we have $F_3 = F_{11}$ and $F_0 = F_{21}$, so we obtain the statistics of $F_3$, $F_0$ from those of $F_{11}$, $F_{21}$. Eqs. (4) are thus independent of $\theta$. The Liapunov exponent is therefore determined by solving a pair of coupled stochastic differential equations for $(Y_1, Y_2)$.

To make further progress we must specify the statistical properties of the isotropic and homogeneous random field $f$. We consider the case where $\langle f \rangle = 0$. Without loss of generality we can write

$$f(r, t) = \nabla \phi(r, t) + \nabla \cdot \hat{n}_3 \psi(r, t)$$

where $\hat{n}_3$ is a unit vector pointing out of the plane. The components of $f$ arising from $\phi$ and $\psi$ are termed the potential and solenoidal components, respectively.

In the following we assume that the correlation function $C(R, \Delta t) = \langle \phi(r, t)\phi(r', t') \rangle$ is an even function of $\Delta t = t - t'$ with support $\tau$ (the correlation time), and has support $\xi$ (the correlation length) in $R = |r - r'|$. We also assume, for simplicity, that the fields $\phi$ and $\psi$ are not correlated with each other, and have the same correlation functions, apart from a scale factor $\alpha^2 = \langle \psi^2 \rangle / \langle \phi^2 \rangle$. These assumptions are easily relaxed.

If the correlation time $\tau$ is short compared to other relevant time scales we can write (4) as a pair of coupled Langevin equations. We scale these into a dimensionless form, in which the diffusion matrix is the unit matrix

$$dx_i = \left[ -x_i + \epsilon(\Gamma x_i^2 - x_i^4) \right] dt' + \sigma_i d\xi_i,$$

$$dx_2 = \left[ -x_2 - 2x_1x_2 \right] dt' + \sigma_2 d\xi_2.$$

Here $x_i = \sqrt{\gamma/D_i} Y_i$ (for $i = 1, 2$), $t' = \gamma t$, $\langle d\xi_i d\xi_j \rangle = 2\delta_{ij} d\xi'$, and

$$D_i = \frac{1}{2} \int_{-\infty}^{\infty} dt \langle F_{11}(t) F_{11}(0) \rangle.$$

The two parameters $\Gamma$ and $\epsilon$ are defined as follows:

$$\Gamma \equiv D_2/D_1 = (1 + 3\alpha^2)/(3 + \alpha^2)$$

characterises the ratio of the solenoidal and potential field amplitudes, $\frac{1}{3} \leq \Gamma \leq 3$, with $\Gamma = \frac{1}{3}$ for purely solenoidal fields, $\Gamma = 3$ for purely potential fields, and $\Gamma = 1$ for equal field intensities. The second parameter

$$\epsilon = D_1^{1/2}/(m\gamma^{3/2}) = (mD_1)^{1/2}/(6\pi \eta a)^{3/2}$$

is a measure of the importance of inertial effects in the equation of motion.

The Langevin equations (7) are equivalent to a Fokker-Planck equation [8]

$$\frac{\partial P}{\partial t} = \hat{F} P = \nabla \cdot [-\nabla P + \nabla\hat{F}]$$

where the advection field $\hat{F}$ has components $V_1 = -x_1 + \epsilon(\Gamma x_1^2 - x_1^4)$ and $V_2 = -x_2 - 2x_1x_2$. We write $\hat{F} = \hat{F}_0 + \epsilon \hat{F}_1$ and seek a steady-state solution $P$ satisfying $\hat{F} P = 0$. The Liapunov exponent $\lambda_1$ is determined by computing $\langle x_1 \rangle$ with $P(x)$, and using (2) to obtain $\lambda_1 = \gamma \epsilon \langle x_1 \rangle$.

We start by considering a perturbative approach. In the limit $\epsilon \to 0$ the steady-state solution is

$$P_0(x) = A \exp[-\frac{1}{2}(x_1^2 + x_2^2)] \equiv A \exp[-\Phi_0(x)].$$

It is convenient to make a transformation of the Fokker-Planck operator $\hat{F}$ to a new operator $\hat{H}$ of the form $\hat{H} = \Phi_0/2 F_0 \Phi_0(2F_0)^{-1}$, and obtain, for $\hat{H}_0,

$$\hat{H}_0 = \hat{H}_0 + \gamma \hat{H}_1 + \hat{H}_2.$$
with \( c_1 = 1, c_2 = 5, c_3 = 60, c_4 = 1105, c_5 = 27120, c_6 = 828250, \ldots \) This predicts that the Liapunov exponent is positive (non-coagulating phase) for \( \Gamma > 1 \) and negative for \( \Gamma < 1 \), independent of \( \epsilon \). Fig. 2d shows that this surprising prediction is indeed false.

It is possible that the Liapunov exponent may have a component non-analytic at \( \epsilon = 0 \), not captured by perturbation theory. The series \( \Phi \) is asymptotic and should be truncated at the smallest term, with index \( k^* \). The coefficients satisfy the recursion \( c_k = (6k-8)c_{k-1} + \sum_{l=1}^{k-1} c_l c_{k-l} \) with \( c_0 = -1/2 \), and we find

\[
c_k \sim 3^k \sqrt{2k!} \tag{17}
\]

for \( k \to \infty \), so that \( k^* \sim 1 + \text{Int}\{1/[6(1-\Gamma)e^2]\} \). We apply a principle expounded by Dingle [4], which suggests that the error of an asymptotic series is comparable to its smallest term. This approach indicates that in the limit \( \epsilon \to 0 \) the non-analytic term is of the form \( \lambda_1 \sim C \exp[-1/6(1-\Gamma)e^2] \) (where \( C \) might have a power-law dependence on \( \epsilon \)). This still incorrectly predicts that the non-analytic contribution vanishes at \( \Gamma = 1 \), so that the phase line is independent of \( \epsilon \).

We have therefore used an alternative approach: we write \( P = A \exp(-\Phi) \) so that \( \Phi \) must satisfy

\[
\nabla^2 \Phi - \nabla \cdot V - \nabla \Phi - (\nabla \Phi)^2 = 0 . \tag{18}
\]

The deterministic advection velocity field \( V \) contains terms which are quadratic in \( x \). This suggests that \( \Phi \) is bounded by a cubic in \( x \). In (18), the first two terms are expected to be bounded by multiples of \( |x| \), whereas the remaining terms are expected to be bounded by a cubic function of \( |x| \). We expect that close to the origin, the solution is well approximated by \( \Phi \sim \Phi_0 = \frac{1}{2}(x_1^2 + x_2^2) \), and that far from the origin \( \Phi \) is well approximated by the solution of the equation containing only the leading-order terms, i.e. \( V \cdot \nabla \Phi + (\nabla \Phi)^2 = 0 \). This has the form of a Hamilton-Jacobi equation \( H(\Phi_0, \nabla \Phi) = E \), where in our case \( E = 0 \) and where the Hamiltonian is \( H(x,p) = V(x) \cdot p + p^2 \). The Hamilton-Jacobi equation is solved by integrating Hamilton’s equations, then \( \Phi \) is obtained by integration along the trajectories: \( \Phi(x) = \int^t dt \cdot p(x) \). We start classical trajectories infinitesimally close to the origin with initial conditions \( p = V \Phi = x \), integrate them numerically, investigate the form of the trajectories, and determine the action function \( \Phi(x) \). We are especially interested in singularities of \( \Phi \), because these are expected to lead to non-analytic behaviour of the Liapunov exponent.

On the \( x_1 \)-axis, for \( p_2 = 0 \), the vectors \( \dot{x} \), \( V \) and \( x \) are parallel, and \( p = -V \). This trajectory crosses a singularity at the point \( x^* = (-1/\epsilon, 0) \), at which both \( V \) and \( p \) vanish, with action \( \Phi(-1/\epsilon, 0) = 1/(6e^2) \). For \( 0 < \Gamma < 2 \) our numerical experiments did not identify any other singular point with a smaller value of \( \Phi \). Consider the physical significance of this singular point in terms of the dynamics of a fictitious particle with position \( x(t) \) described by the Langevin equation (7). A typical trajectory is plotted in Fig. 2a. The advection field \( V \) has an unstable fixed point at \( x^* \). To the right of the singularity, the particle is advected back towards the origin, and the probability density decreases rapidly as the fixed point is approached from that direction. To the left of the singularity, the particle is advected away, following the advection field \( V \); initially it moves to the left, returning to large positive \( x_1 \) in a large circuit. The singularity is therefore associated with diffusive escape from the attractor of \( V \) at \( x = 0 \), in which the escaping particle is initially advected away, but returns along paths close to the positive \( x_1 \) axis. This leads to the hypothesis that there should be a contribution to \( \lambda_1 \) proportional to \( \exp[-\Phi(x^*)] = \exp[-1/(6e^2)] \), where the prefactor may have an algebraic dependence on \( \epsilon \).

According to our numerical results, the dominant correction to the perturbation series in the limit \( \epsilon \to 0 \) does indeed arise in this way: we find

\[
\lambda_1 / \gamma \sim \chi(\Gamma) \exp[-1/(6e^2)] - \sum_{k=1}^{k^*} c_k (1-\Gamma)e^{2k}. \tag{19}
\]

We have not been able to determine the form of the prefactor \( \chi \) analytically: it appears to be independent of \( \epsilon \). In Fig. 2d we compare the Monte-Carlo simulations of (7) with (19). Fig. 2e shows the phase diagram, as de-
determined using [12] and Monte-Carlo simulation of [10]. The computed curve is compared with an empirical fit, using the exponential function $\exp[-1/(6c^2)]$ which characterises the escape process.

The coefficients in [13] also occur in the asymptotic expansion of $Ai'(z)/Ai(z)$ [11]. This suggests that $\lambda_1/\gamma = -\text{Re} \left[ Ai'(z)/Ai(z) + \sqrt{z}/(2\sqrt{2}) \right]$ with $z = (i\sqrt{1-\Gamma})e^{-4/3}/4$. This expression cannot be correct for $|1-\Gamma| < 1$, because its leading order non-analytic correction becomes smaller than the non-analytic term in [10] in the limit $\epsilon \to 0$. However, on setting $\Gamma = 0$, we find that it does agree with the exact solution of the one-dimensional problem obtained in [2], and our numerical results show excellent agreement with Monte-Carlo simulations when $\Gamma = 2$ (where we believe that it could also be exact), and when $\Gamma = 3$.

In summary, we have seen that the theory of coagulation by random velocity fields bears several surprises. We have seen that the phase transition is determined by the stationary state of a Langevin process. Perturbation theory incorrectly predicts that the phase line is independent of the inertia parameter $\epsilon$. The asymptotics of the high order terms of the perturbation series again do not predict the correct form of the non-analytic term; we are not aware of any other physical example where this procedure fails (although a mathematical example was suggested in [12]). Finally, the path-coalescence phase transition is driven by a non-analytic term characterising the flux of a barrier in a Kramers problem.

We conclude with a number of remarks and a discussion of possible applications of the effect. First, in many applications the suspended particles will not have equal masses, and it is necessary to consider how mass dispersion affects the coagulation process. We have shown, in a perturbative framework, that two particles with masses differing by $\delta m \ll m$ follow trajectories with separation $\Delta r_t = \delta m g(t)$, where $(g(t))^2$ remains bounded as $t \to \infty$. We infer that when the masses are unequal, particles condense onto fragmented line segments rather than isolated points. The coagulation effect is therefore weakened, but not destroyed (Fig. 3) by mass dispersion. Second, the structures observed in Fig. 1 indicate that the area-contraction rate is much larger than the maximal Liapunov exponent $\lambda_1$. We have verified this by computing the Liapunov spectrum $\lambda_4 < \lambda_3 < \lambda_2 < \lambda_1$ of (1) numerically (the area-contraction rate is given by $\lambda_2 + \lambda_1$). Similar structures were observed in computer simulations of inertial particles in a chaotic flow [6]. In two dimensions, $\lambda_2$ can be found from the stationary state of Langevin equations similar in structure to (7).

Turning to specific applications, we note that the random velocity field $u(r,t)$ could arise from random sound waves, turbulent flow, or other random disturbances. We do not know how to estimate $\Gamma$ reliably for turbulent flow in gases. In the case of liquids where the flow is incompressible, our theory applies when the suspended particles are denser that the fluid: we predict there is no coagulation because $\Gamma > 1$. In sound waves the velocity field is proportional to the pressure gradient, and is therefore pure potential: $\Gamma = \frac{4}{3}$, so according to Fig. 2 there is a coagulating phase. One possible technological application of the effect would be to the coagulation of small pollutant particles in an engine exhaust. An ultrasonic noise source could increase the size of the pollutant particles until they are large enough to be captured efficiently by a mechanical filter. Coagulation by ultrasonic sources has been observed experimentally [13]. Theoretical treatments, reviewed in [13], have considered the case where the ultrasound has a single frequency, and the coagulation results from particles with differing masses experiencing different displacements. This letter has introduced a new mechanism for ultrasonic coagulation, which works even when particles have the same mass.
