Abstract

The simple stationary decoherence of a two-state quantum system is discussed from a new viewpoint of environmental entanglement. My work emphasizes that an unconditional local state must totally be disentangled from the rest of the universe. It has been known for long that the loss of coherence within the given local system is gradual. Also the quantum correlations between the local system and the rest of the universe are being destroyed gradually. I show that, differently from local decoherence, the process of environmental disentanglement may terminate in finite time. The time of perfect disentanglement turns out to be on the decoherence time scale, and in a simple case we determine the exact value of it.
I. INTRODUCTION

Perfect isolation of a real physical system $S$ is not possible. Even the simplest quantum system, like the spin of an electron, may be in weak though continuous interaction with the environment $E$. The sensitivity of quantum systems to environmental interactions goes beyond the sensitivity of classical systems. In our example, the coherence of local superpositions will asymptotically be lost at a certain decoherence time scale $\tau$. We consider the simplest isotropic model of environmental decoherence of a Pauli-spin vector $\vec{\sigma}$:

$$\frac{d\rho}{dt} = -\frac{1}{4\tau} [\vec{\sigma}, [\vec{\sigma}, \rho]],$$

(1)

where $\rho$ is the $2 \times 2$ density matrix of the spin. This equation may, e.g., correspond to the proper statistical average of the Schrödinger-equation

$$\frac{d\psi}{dt} = -\frac{i}{2} \vec{\omega} \vec{\sigma} \psi$$

(2)

over the random magnetic field $\vec{\omega}$ which is $\tau^{-1/2}$-times the standard isotropic white-noise. The solution $\rho(t)$ encodes the statistics of all possible local phenomena, i.e., the physics of the spin. It is, nonetheless, known from the famous work of John Bell [2] that quantum correlations with remote systems paralyze the standard statistical interpretation of the local state $\rho$. We are going to analyze the fate of such external quantum correlations of our local system during its irreversible evolution (1). We recapitulate the definition of quantum correlation (entanglement) through the notion of separability [3]. We can prove that all external quantum correlations will disappear if and only if

$$t \geq \tau \log 3.$$  

(3)

The result comes from a recent theorem on ‘entanglement breaking quantum channels’ [4, 5, 6]. I will present an elementary alternative proof. We shall mention a contrary case:

$$\frac{d\rho}{dt} = -\frac{1}{\tau} [\sigma_3, [\sigma_3, \rho]].$$

(4)

This is continuous measurement of the $\sigma_3$ spin-component where the total damping of external quantum correlations takes an infinite long time.

II. SEPARABILITY, ENTANGLEMENT, STATISTICAL CONSISTENCY

To study the structure of the external correlations of our system, we divide the universe $U$ into three parts: the local system $S$ of interest, its environment $E$ responsible for the irreversible
evolution \( \mathcal{E} \), and the rest \( \mathcal{R} \) which has no current interaction with \( S \) but might have had it in the remote past. This time we concentrate on the correlations between \( S \) and \( \mathcal{R} \). We do not consider \( \mathcal{E} \) a dynamical system at all. We model it merely as a source of classical magnetic noise leading to the irreversible equation \( (1) \) for the local system \( S \). One says that the local system is **classically correlated** with the rest of the universe if the total quantum state is **separable** \( [3] \):

\[
\rho_U = \sum_{\lambda} w^\lambda \rho^\lambda \otimes \rho^\lambda_{\mathcal{R}},
\]

i.e., it is the weighted mixture of uncorrelated (product) states.

Such an expansion is always possible for correlated classical systems. Their density matrices are always diagonal. For the corresponding classical densities the separability condition \( [5] \) reads:

\[
\rho_U(x,X) = \sum_{\lambda} w^\lambda \rho^\lambda(x) \rho^\lambda_{\mathcal{R}}(X),
\]

where \( x \) and \( X \) label the states of the classical systems \( S \) and \( \mathcal{R} \), respectively. To construct the r.h.s., first we identify \( \lambda \) by the composite label \( (x',X') \) and we identify \( w^\lambda \) by \( \rho_U(x',X') \). Then we can make the choices \( \rho^\lambda(x) = \delta(x-x') \) and \( \rho^\lambda_{\mathcal{R}}(X) = \delta(X-X') \).

Quantum systems differ radically. They may not satisfy the separability \( [5] \). By definition, the local system \( S \) is **quantum-correlated** (entangled) with the rest \( \mathcal{R} \) of the universe if the composite state \( \rho_U \) is non-separable. Most typically, this is the case when the universe is in a pure state \( \rho_U = |U\rangle \langle U| \) which is not a product state:

\[
|U\rangle \neq |S\rangle \otimes |\mathcal{R}\rangle.
\]

Why do any sort of correlation with the remote part of the universe should bother our observations on the local system? The reason is tricky. If the separability condition \( [5] \) holds then the correlation between local phenomena in \( S \) and remote phenomena in \( \mathcal{R} \) can in principle be explained on the ground of classical statistics \( [3] \). If, however, the separability condition does not hold then the local and remote phenomena may become inconsistent from the viewpoint of classical statistical rules unless we allow instantaneous signal propagation between the local and remote systems \( S \) and \( \mathcal{U} \), respectively \( [2] \). Such faster-than-light propagation is impossible because it contradicts to our notion of locality. The external quantum-correlations (entanglements) of a local system will thus object that the usual statistical interpretation of the local system be consistent with the simultaneous statistical interpretation of other possible systems populating the rest of the universe. It is therefore not possible to claim that \( \rho \) is the unconditional local state unless we make sure that the local system \( S \) is totally disentangled from the rest \( \mathcal{R} \) of the universe. There should be no quantum correlations left between them.
III. TOTAL DISENTANGLEMENT

We shall discuss the existence and fate of the external quantum correlations of our chosen system. The formal solution of the equation (1) contains a linear time-dependent map $\mathcal{M}(t)$:

$$\rho(t) = \mathcal{M}(t)\rho(0).$$

The state $\rho(t)$ does obviously not encode external correlations, i.e., those between the two-state system $S$ and the rest of the universe $R$. The generic state $\rho_U$ does not satisfy the separability condition (5) because usually it contains quantum correlations between $S$ and $R$. So does the initial state $\rho_U(0)$. Surprisingly, a recent theorem [4, 5, 6] enables us to conclude that after a finite threshold time the state $\rho_U(t)$ becomes totally separable, i.e., the local system $S$ disentangles from the rest $R$ of the universe. The power of the theorem lies in that it needs only the local map $\mathcal{M}(t)$ though with the tacit assumption that $S$ and $R$ evolve independently.

Accordingly, a certain map $\mathcal{M}$ will completely disentangle the local system if and only if it acts as follows:

$$\mathcal{M}\rho = \sum_\lambda p^\lambda \rho^\lambda,$$

$$p^\lambda = \text{tr}[P^\lambda \rho],$$

(9)

where $\{\rho^\lambda\}$ is a certain set of states that does not depend on the original state $\rho$. The mixing probabilities $\{p^\lambda\}$ depend on $\rho$ via a generalized measurement, i.e., the set $\{P^\lambda\}$ must be a positive-operator-valued-measure (POVM) [8]:

$$P^\lambda \geq 0,\quad \sum_\lambda P^\lambda = I.$$

(10)

One confirms easily that the above conditions are sufficient for the separability of the mapped composite state. Recall that we assumed independent maps for $S$ and $R$:

$$\mathcal{M}_{U\rho_U} = (\mathcal{M} \otimes \mathcal{M}_R) \rho_U.$$

(11)

By inserting $\mathcal{M}$ from Eq. (9), where we set

$$p^\lambda = \text{tr}\left[ (P^\lambda \otimes \mathcal{M}_R)\rho_U \right],$$

$$\rho^\lambda_R = \frac{1}{p^\lambda} \text{tr}_S\left[ (P^\lambda \otimes \mathcal{M}_R)\rho_U \right],$$

(12)

the separable form (5) is obtained for $\mathcal{M}_{U\rho_U}$. The proof of necessity of the condition (9) is a harder task.
IV. THE DISENTANGLEMENT TIME

Let us test the condition (9) on the map $\mathcal{M}(t)$ solving the Eq. (1) for $t \geq 0$. The identical map $\mathcal{M}(0)$ can of course never admit the form (9). Neither does $\mathcal{M}(t)$ at short times. But a threshold time will exist after which the map $\mathcal{M}(t)$ can already be written into the desired form (9). The irreversible equation (1) describes an exponential isotropic depolarization. Its solution (8) can be written into this concrete form:

$$\rho(t) \equiv \mathcal{M}(t)\rho(0) = \frac{1}{2} \left[ I + e^{-t/\tau} \vec{\sigma} \text{tr}[\vec{\sigma} \rho(0)] \right].$$  \hspace{1cm} (13)

If follows from a theorem in Ref. [6] that the map $\mathcal{M}(t)$ is entanglement breaking if and only if $3e^{-t/\tau} \leq 1$ which is the condition (3). Here I present a constructive proof. In order to put the time-dependent map $\mathcal{M}(t)$ into the desired form (9), let us try the following. We assume the set $\{\rho^\lambda\}$ to consist of six states labeled by $\lambda = (\alpha, s)$:

$$\rho^{\alpha s} = \frac{1}{2} \left[ I + 3se^{-t/\tau} \sigma_\alpha \right],$$  \hspace{1cm} (14)

where $\alpha = 1, 2, 3$ while $s = \pm 1$ in turn. Let the corresponding six POVM elements be proportional to six different completely polarized pure state projectors:

$$P^{\alpha s} = \frac{1}{6} \left[ I + s\sigma_\alpha \right].$$  \hspace{1cm} (15)

By inserting the Eqs. (14,15) into (9), we obtain the solution (13) indeed. However, a closer look at the Eq. (14) warns us that the states $\rho^{\alpha s}$ do not exist until the absolute value of the coefficient $3e^{-t/\tau}$ descends from the initial value 3 to 1. This completes our proof. The map $\mathcal{M}(t)$ disentangles any initial state $\rho(0)$ from the rest of the universe after time (3).

Let us assume that $\mathcal{R}$ is just another two-state system and its evolution is trivial: it does not evolve at all. Then the composite state satisfies the trivial extension of the local evolution equation (1):

$$\frac{d\rho_\mathcal{R}}{dt} = -\frac{1}{4\tau} \left[ \vec{\sigma} \otimes I_\mathcal{R}, [\vec{\sigma} \otimes I_\mathcal{R}, \rho_\mathcal{R}] \right].$$  \hspace{1cm} (16)

Assuming the initial composite state $\rho_\mathcal{R}(0)$ is the maximally entangled singlet state, we can find the following time-dependent solution:

$$\rho_\mathcal{R}(t) = \frac{1}{4} \left[ I \otimes I_\mathcal{R} - e^{-t/\tau} \vec{\sigma} \otimes \vec{\sigma} \right].$$  \hspace{1cm} (17)

This state remains entangled for $e^{-t/\tau} > 1/3$ (c.f. 3) which shows that the threshold (3) can not be sharpened.
V. DISCUSSION AND OUTLOOK

I have analyzed the simplest case of noisy environment (1) which is capable to destroy all external quantum correlations of a local system in finite time (3). It is important to note that classical correlations may survive the death of quantum ones. The studied environment is classical and non-dynamical, its simplest realization is an isotropic classical magnetic white-noise field. The corresponding map is called the ‘depolarizing channel’ in quantum communication theory (10). There is a non-isotropic environment producing decoherence on the same time scale as Eq. (1) did but with a different structure (4). This is called the ‘measurement channel’ since for infinite time it describes the ideal measurement of the spin-component $\sigma_3$. Obviously it disentangles the local system $S$ from $R$ at time $t = \infty$ as any ideal spin-measurement should. Regarding finite times, however, the external quantum correlations may always survive. When I tried the sort of constructive proof, successful for the ‘depolarizing channel’ (1), it failed for the ‘measurement one’ (4). An ultimate proof may be learned in Ref. (6): the ‘measurement channel’ only eliminates external quantum correlations at $t = \infty$, i.e., not before the ideal measurement is completed. Recently, I have found a third, affirmative, example. From earlier results of Kiefer and myself (9) on the emergent exact positivity of the Wigner- and the P-functions, it follows that a free particle in simplest position decohering environment will become disentangled in finite time. This result may certainly be extended for the broader class (12) of evolution equations including harmonic potential and friction as well.

For future investigations, the generic problem can be formulated in the following way. Suppose the environment induces a semi-group evolution for the local system, described by the generator $\mathcal{L}$ (11):

$$\frac{d\rho}{dt} = \mathcal{L}\rho , \quad (18)$$

We construct the time-dependent map of the semi-group:

$$\mathcal{M}(t) = \exp(\mathcal{L}t) , \quad (19)$$

which solves the evolution equation. Then one has to apply the condition (9) to the above map in order to determine if it disentangles in finite/infinite time or whether it disentangles at all.
Acknowledgment(s)

I am grateful to the organizers and sponsors of the conference on ”Irreversible Quantum Dynamics” for the invitation to talk in Triest and to contribute to this volume. My research was also supported by the Hungarian OTKA Grant No. 032640.
