The mixed search game against an agile and visible fugitive is monotone

Guillaume Mescoff† Christophe Paul† Dimitrios M. Thilikos†

Abstract

We consider the mixed search game against an agile and visible fugitive. This is the variant of the classic fugitive search game on graphs where searchers may be placed to (or removed from) the vertices or slide along edges. Moreover, the fugitive resides on the edges of the graph and can move at any time along unguarded paths. The mixed search number against an agile and visible fugitive of a graph $G$, denoted $avms(G)$, is the minimum number of searchers required to capture a fugitive in this graph searching variant. Our main result is that this graph searching variant is monotone in the sense that the number of searchers required for a successful search strategy does not increase if we restrict the search strategies to those that do not permit the fugitive to visit an already “clean” edge. This means that mixed search strategies against an agile and visible fugitive can be polynomially certified, and therefore that the problem of deciding, given a graph $G$ and an integer $k$, whether $avms(G) \leq k$ is in NP. Our proof is based on the introduction of the notion of tight bramble, that serves as an obstruction for the corresponding search parameter. Our results imply that for a graph $G$, $avms(G)$ is equal to the Cartesian tree product number of $G$, that is, the minimum $k$ for which $G$ is a minor of the Cartesian product of a tree and a clique on $k$ vertices.

Keywords: Graph searching game, bramble, Cartesian tree product number, tree decomposition.

1 Introduction

A search game on a graph is a two-player game opposing a fugitive and a group of searchers. The searchers win if they capture the fugitive, while the fugitive’s objective is to avoid capture. The searchers and the fugitive play in turns. Search games on graphs were originally been introduced by Parsons [17] who defines the edge search number of a graph as the minimum number of searchers required to capture a fugitive moving along the edges. To capture the fugitive, a search program is seen as a sequence of searchers’ moves. A move consists in either adding a searcher on a vertex, removing a searcher from a vertex or sliding a searcher along an edge. The fugitive is allowed to move along the edges of paths that are free of searchers. The edge search number is then the minimum number of searchers required to capture the fugitive (that is, the fugitive cannot escape through an unguarded path).

During the last decades, a large number of variants of seminal Parsons’ edge search game have been studied. Each of these variants depends on the fugitive and searchers abilities. For example, the fugitive can be visible to the searchers or invisible. It can also be lazy, then it stays at its location as long it is not directly threatened by the searchers, or agile, then it may change its location at every round. Where the fugitive resides (on edges or on vertices), whether the searchers are allowed to slide on edges or not, how the fugitive is captured are other criteria used to define search game variants (see [8, 15] for surveys).

The theory of search games on graphs is strongly connected to the theory of width parameters and graph decompositions. It is well known that the node search number of a graph against an agile but visible fugitive corresponds to the treewidth of that graph [19]. The same equivalence also holds for the case of the node search number against a lazy but invisible fugitive [5]. The node search variant
where the fugitive is agile and invisible corresponds to the **pathwidth** \[^{12,11,6}\]. These three variants are usually defined as node search games as the searchers cannot slide along an edge and the fugitive is located on vertices rather than on edges. In the case of agile but visible fugitive (respectively lazy but invisible fugitive), the existence of an escape strategy for the fugitive can be derived from the existence of a **bramble** of large order \[^{19}\] which is a certificate of large treewidth. Likewise, in the case of agile and invisible, a large **blockage** certifies a large pathwidth and allows an escape strategy \[^{3}\].

Interestingly, a consequence of the equivalences discussed above between search numbers and width parameters is that the corresponding games can be proved to be **monotone**. Intuitively, a game is monotone if it allows to optimally search a graph without recontamination of the previously cleared part of the graph. Monotonicity is an important property as it implies that the problem of deciding the corresponding search number of a graph belongs to **NP** (see \[^{8}\] for a discussion about monotonicity).

**Our results.** In this paper, we consider the so-called **mixed search game against an agile and visible fugitive**. In this variant, the fugitive resides on the edges and the searchers can capture the fugitive either by sliding along the edge location it resides or by occupying the two vertices incident to that edge location (see Subsection 2.5 for formal definitions). Up to our knowledge, the monotonicity issue of a mixed search game was only proved in the case of an agile and invisible fugitive \[^{4}\]. We prove that the mixed search game against an agile and visible fugitive is monotone. To that aim, we first show that the corresponding search number of a graph is equal to the **Cartesian tree product number** of that graph \[^{10}\], also known as the **larger d’arborescence** \[^{22}\]. To certify these two parameters, we introduce the notion of **loose tree-decomposition** which is a relaxation of the celebrated tree-decomposition associated to tree-width. This allows us to define the notion of **tight bramble** as the min-max counterpart of Cartesian tree product number. Then the monotonicity of the mixed search game against an agile and visible fugitive is obtained by proving that the existence of a tight bramble allows an escape strategy for the fugitive, while the existence of a loose tree-decomposition of a small width allows to derive a monotone search strategy of small cost.

## 2 Preliminairies

### 2.1 Basic concepts

In this paper, all graphs are finite, loopless, and without multiple edges. We denote by \(V(G)\) the set of the vertices of \(G\) and by \(E(G)\) the set of the edges of \(G\). We use notation \(xy\) in to denote an edge \(e = \{x, y\}\). Given a edge \(xy \in E(G)\), we define \(G - xy = (V(G), E(G) \setminus \{xy\})\). The graph resulting from the removal of a vertex subset \(S\) of \(V(G)\) is denoted by \(G - S\). If \(S = \{v\}\) is a singleton we write \(G - v\) instead of \(G - \{v\}\). We define the subgraph of \(G\) induced by \(S\) as the graph \(G[S] = G - (V(G) \setminus S)\). We say that \(S\) is connected (in \(G\)) if \(G[S]\) is connected. A subset \(S\) of \(V(G)\) is a separator of \(G\) if \(G - S\) contains more connected components than \(G\). We say that \(S\) separates \(X \subseteq V(G)\) from \(Y \subseteq V(G)\) if \(X\) and \(Y\) are subsets of distinct connected components of \(G - S\).

Contracting an edge \(e = xy\) in a graph \(G\) yields the graph \(G_{/e}\) where \(V(G_{/e}) = V(G) \setminus \{x,y\}\cup\{v_x\}\) and \(E(G_{/e}) = \{uv \in E(G) \mid \{u,v\} \cap \{x,y\} = \emptyset\} \cup \{v_x v \mid xv \in E(G)\text{ or } y v \in E(G)\}\). A graph \(H\) is a minor of a graph \(G\), which is denoted \(H \preceq G\), if \(H\) can be obtained from \(G\) by a series of vertex or edge deletions and edge contractions. It is well known that if \(H \preceq G\), then there exists a minor model of \(H\) in \(G\), that is a function \(\rho : V(H) \to 2^{V(G)}\) such that:

1. for every \(x \in V(H)\), the set \(\rho(x)\) is connected in \(G\); and
2. for every distinct vertices \(x,y \in V(H)\), \(\rho(x) \cap \rho(y) = \emptyset\); and
3. for every edge \(xy \in E(H)\), there exists an edge \(x'y' \in E(G)\) with \(x' \in \rho(x)\) and \(y' \in \rho(y)\).

Given a set \(S\), a **sequence of subsets** of \(S\) is defined as \(S = \langle S_1, \ldots, S_{i} \rangle\) with \(i \geq 1\), where for every \(i \geq 1\), \(S_{i} \subseteq S\). The symmetric difference between two sets \(A\) and \(B\) is denoted by \(A \oplus B\).

A pathway \(\mathcal{W}\) in a graph \(G\) is a sequence \(\mathcal{W} = \langle e_1, e_2, \ldots, e_\ell \rangle\) of edges of \(G\) such that if \(\ell > 1\), then for every \(i \in [\ell - 1]\), the edges \(e_i\) and \(e_{i+1}\) are distinct and incident to a common vertex (that is,
We refer to the vertices of $D$ associated to the tree-width of a graph.

The next lemma shows that every loose tree-decomposition can be turned into a full one of the same width.

\begin{definition}
Let $T$ be a tree and $k$ be a strictly positive integer. We use $K_k$ in order to denote the complete graph on $k$ vertices. We let $T^{(k)} = T \Box K_k$ denote the cartesian product of $T$ with $K_k$, that is: $T^{(k)}$ is the graph with vertex set \{$(x, i) \mid x \in V(T), i \in [k]$\} and with an edge between $(x, i)$ and $(y, j)$ when $x = y$, or when $xy \in E(T)$ and $i = j$ (see Figure 1).
\end{definition}

\textbf{Figure 1:} The cartesian product $T^{(3)} = T \Box K_3$ of a tree $T$ and the clique $K_3$.

\begin{definition}
\textbf{[10, 22]} The cartesian tree product number of a graph $G$ is
\[\text{ctp}(G) = \min\{k \in \mathbb{N} \mid G \preceq T^{(k)}\} .\]
Observe that for any tree $T$, as $T = T \Box K_1$, $\text{ctp}(T) = 1$. In \textbf{[10]}, it is shown that the cartesian tree product number of a graph is equal to the largeur d’arborescence of that graph, a parameter introduced by Yves Colin De Verdière in \textbf{[22]}.
\end{definition}

\subsection{2.3 Loose tree-decomposition}

The concept of loose tree-decomposition is a relaxation of the celebrated \textit{tree-decomposition} \textbf{[9, 18]} associated to the tree-width of a graph.

\begin{definition}[Loose tree-decomposition]
Let $G = (V, E)$ be a graph. A loose tree-decomposition is a pair $D = (T, \chi)$ such that $T$ is a tree and $\chi: V(T) \to 2^{\chi(G)}$ satisfying the following properties:

\begin{enumerate}
\item [L1] for every vertex $x \in V(G)$, the set $\{t \in V(T) \mid x \in \chi(t)\}$ induces a non-empty connected subgraph, say $T_x$, of $T$. We call $T_x$ the trace of $x$ in $D$;
\item [L2] for every edge $e = xy \in E(G)$, there exists a tree-edge $f = \{t_1, t_2\} \in E(T)$ such that $e \in E(G[\chi(t_1) \cup \chi(t_2)])$;
\item [L3] for every tree-edge $f = \{t_1, t_2\}$, $\lvert E(G[\chi(t_1) \cup \chi(t_2)]) \setminus (E(G[\chi(t_1)] \cup E(G[\chi(t_2)])) \rvert \leq 1$.
\end{enumerate}

We refer to the vertices of $T$ as the nodes and to their images via $\chi$ as the bags of the loose tree decomposition $D = (T, \chi)$. The width of a loose tree-decomposition $D = (T, \chi)$ of a graph $G$ is defined as $\text{width}(D, G) = \max\{\lvert \chi(t) \lvert \mid t \in V(T)\}$.

\textbf{Figure 2} provides an example of a loose tree-decomposition. Hereafter, if $D = (T, \chi)$ is a loose tree-decomposition of $G$, and $xy \in E(G[\chi(t_1) \cup \chi(t_2)]) \setminus (E(G[\chi(t_1)] \cup E(G[\chi(t_2)]))$ for some adjacent nodes $t_1$ and $t_2$ (see condition \textbf{(L3)} above), then $xy$ is called a marginal edge. We now examine important properties of loose tree-decompositions that will be used in further proofs.

\begin{figure}
\centering
\includegraphics[width=\textwidth]{figure2}
\caption{Diagram of a loose tree-decomposition.}
\end{figure}

A loose tree-decomposition $D = (T, \chi)$ of width $k \in \mathbb{N}$ is full if for every node $t \in V(T)$, $\lvert \chi(t) \rvert = k$ and if for every pair of adjacent nodes $t$ and $t'$ in $T$, $\chi(t) \cap \chi(t') = \{x, x'\}$ with $x \in \chi(t)$ and $x' \in \chi(t')$. The next lemma shows that every loose tree-decomposition can be turned into a full one of the same width.
Lemma 1. Given a loose tree-decomposition $D = (T, \chi)$ of a graph $G$, one can compute a full loose tree-decomposition $D' = (T', \chi')$ of $G$ such that $\text{width}(D, G) = \text{width}(D', G)$.

Proof. Suppose that $\text{width}(D, G) = k$. We can assume that in $D$, if two nodes $t, t'$ of $T$ are adjacent, then neither $\chi(t) \subseteq \chi(t')$ nor $\chi(t') \subseteq \chi(t)$. Let $t \in V(T)$ be a node such that $|\chi(t)| = k$. Suppose there exists a node $t' \in V(T)$ adjacent to $t$ such that $|\chi(t')| < k$. As there is at most one marginal edge $e$ between $t$ and $t'$, it is possible to add vertices from $\chi(t)$ that are not incident to $e$ to complete $\chi(t')$ to a bag of size $k$. Observe that completing every bag of $T$ that way does not violate the conditions of \textbf{Definition 2}.

We can process all the nodes of $D$ to obtain a loose tree-decomposition whose bags all have size $k$. Let us assume it is the case for $D$.

Suppose that $t_1$ and $t_2$ are adjacent nodes in $T$ such that $|\chi(t_1) \cap \chi(t_2)| < k - 1$. So there exists $x_1, y_1 \in \chi(t_1) \setminus \chi(t_2)$ and some $x_2, y_2 \in \chi(t_2) \setminus \chi(t_1)$. Since there exists at most one marginal edge between $t_1$ and $t_2$, we can suppose without loss of generality that $x_1, x_2 \notin E(G)$. Then we can remove from $T$ the edge $t_1t_2$ and insert a new node $t$ adjacent to $t_1$ and $t_2$ such that $\chi(t) = (\chi(t_1) \cup \chi(t_2)) \setminus \{x_1, x_2\}$. Again, one can observe that this transformation does not violate the conditions of \textbf{Definition 2}. It follows that processing $T$ as long as it contains a tree-edge on which this transformation applies, yields to transform $D$ into a full loose tree-decomposition $D$ without increasing the width. \hfill $\Box$

Lemma 2. Let $D = (T, \chi)$ be a full loose tree-decomposition of a graph $G$. For every node $t$ that is not a leaf of $T$, $\chi(t)$ is a separator of $G$.

Proof. As $t$ is not a leaf, $T$ contains two nodes $t_1$ and $t_2$ adjacent to $t$. As $D$ is full, there exist $x_1 \in \chi(t_1) \setminus \chi(t)$ and $x_2 \in \chi(t_2) \setminus \chi(t)$. Let $P$ be a path in $G$ between $x_1$ and $x_2$. Let us recall that every edge of $G$ is either a marginal edge between two neighboring nodes of $T$ or incident to two vertices belonging to the bag of some node of $T$. This implies that the set of nodes $\{t \in V(T) \mid t \in T_x, x \in P\}$ induces a connected subtree of $T$. As $t_1$ and $t_2$ belong to that set, so does $t$. It follows that $P$ intersects $\chi(t)$ and thereby $\chi(t)$ is a separator of $G$. \hfill $\Box$

Lemma 3. Let $D = (T, \chi)$ be a full loose tree-decomposition of a graph $G$ and let $\{t_1, t_2\}$ be an edge of $T$. If $\chi(t_1) \cap \chi(t_2) = \{x_1, x_2\} \notin E(G)$, then $\chi(t_1) \cap \chi(t_2)$ is a separator of $G$.

Proof. Suppose that $x_1 \in \chi(t_1) \setminus \chi(t_2)$ and $x_2 \in \chi(t_2) \setminus \chi(t_1)$. We prove that $\chi(t_1) \cap \chi(t_2)$ is a $(x_1, x_2)$-separator. Let $P$ be a path between $x_1$ and $x_2$ in $G$. We let $T_1$ denote the largest subtree of $T$ containing $t_1$ but not $t_2$. Consider the vertex set $V_1 = \{x \in V(G) \mid \exists t \in T_1, x \in \chi(t)\}$. Let $x \in V_1$ and $y \notin V_1$ be the two adjacent vertices of $P$ such that every vertex $z$ of $P$ between $x_1$ and $x$ belongs to $V_1$. As $x_2 \notin V_1$, the vertices $x$ and $y$ are well defined ($x$ may be equal to $x_1$). By \textbf{Definition 2}, every edge is either a marginal edge between two adjacent nodes of $T$ or is contained in the bag of some node of $T$. By assumption, there is no marginal edge between $t_1$ and $t_2$. As $x \in V_1$ and $y \notin V_1$, we have that $x \in \chi(t_1) \cap \chi(t_2)$, and thereby $\chi(t_1) \cap \chi(t_2)$ intersects $P$. \hfill $\Box$
2.4 Tight brambles

In order to define a notion of obstacle to the existence of a loose tree-decomposition of small width, we now adapt the well-known definition of bramble that is used in the context of tree-decomposition and treewidth [19]. Let $G$ be a graph. Two subsets $S_1$ and $S_2$ of $V(G)$ are tightly touching if either $S_1 \cap S_2 \neq \emptyset$ or $E(G)$ contains two distinct edges $x_1x_2$ and $y_1y_2$ such that $x_1, y_1 \in S_1$ and $x_2, y_2 \in S_2$ (the edges $x_1x_2$ and $y_1y_2$ may share one vertex but not two, as graphs are considered to be simple). For simplicity, in this paper we use touching as a shortcut of the term tightly touching.

**Definition 3** (Tight bramble). Let $G$ be a graph. A set $B \subseteq 2^{V(G)}$ of pairwise touching connected subsets of vertices, each of size at least two, is a tight bramble of $G$. A set $S \subseteq V(G)$ is a cover of $B$ if for every set $B \in B$, $S \cap B \neq \emptyset$. The order of the bramble $B$ is the smallest size of a cover of $B$.

![Diagram](image)

Figure 3: On the left, we observe that $B = \{\{a, b\}, \{b, c\}, \{c, d, e, f, a\}\}$ is a tight bramble of order two. On the right, $B_1 = \{\{x, y\} \mid xy \in E(G)\}$ is a tight bramble of order 4 of the $K_4$. Observe that $B_2 = \{\{a\}, \{b, c\}, \{c, d\}, \{b, c\}\}$ is a set of pairwise touching connected subsets of $V(K_4)$. However, according to **Definition 3**, as it contains the singleton set $\{a\}$, is it not a tight bramble. See **Observation 2** and the related discussion.

Let us discuss **Definition 3**. Observe first that, if $G$ is an edge-less graph, then its unique tight bramble is $B = \emptyset$ which has order 0. In the rest of the paper, we will not consider edge-less graphs as searching a fugitive (located on edges) in such a graph would create degenerate situations. The next observation provides a characterization of trees by means of tight brambles.

**Observation 1.** Let $G$ be a connected graph. The maximum order of a bramble of $G$ is 1 if and only if $G$ is a tree.

**Proof.** We observe that if $G$ is a tree, a tight bramble consists of set of pairwise intersecting subtrees of $G$. It follows by the Helly property that the maximum order of a bramble of a tree is 1. Suppose that $G$ is not a tree. Then $G$ contains a cycle $C$ of at least 3 edges. Let $f_1, f_2, \ldots, f_t, t \geq 3$, be the edges the edges of $C$ such that for $1 \leq i < t, f_i \cap f_{i+1} \neq \emptyset$ and $f_i \cap f_1 \neq \emptyset$. Then observe that $B = \{\{f_1\}, \{f_2\}, C \setminus \{f_1, f_2\}\}$ is a tight bramble of order 2 (see Figure 3).

Finally, if we discard edge-less graphs, then we can observe that the size-two constraint on the elements of a tight bramble can be relaxed without changing the value of the maximum order of a tight bramble of a given graph.

**Observation 2.** Let $B \subseteq 2^{V(G)}$ be a set of pairwise touching connected subsets of $V(G)$ containing the singleton set $\{x\}$, for some $x \in V(G)$. If the order of $B$ is $k$, then there exists a tight bramble $B'$ of $G$ of order $k$.

**Proof.** To construct $B'$, we proceed as follows. For every $S \in B$ such that $S \neq \{x\}$, let $ys$ and $zs$ be two vertices of $S$ such that $yxS \in E$ and $xzS \in S$. Then we set $B' = (B \setminus \{x\}) \cup \{\{ys\}, \{zs\} \mid S \in B, S \neq \{x\}\}$. In other words, $B'$ is obtained by replacing $\{x\}$ by every pair of edges $\{yxS\}$ and $\{xzS\}$. Clearly, the order of $B'$ is at most $k$. To see this, consider a cover $X$ of $B$. Observe that $x \in X$ and thereby $X$ is a cover of $B'$ as well. Now assume $B'$ has a cover $X'$ not containing $X$. Let us consider $S \in B \cap B'$. Then $S$ contains two vertices of $S$, namely $ys$ and $zs$. It is easy to see that $X' \setminus \{ys\} \cup \{x\}$ is also a cover of $B'$. It follows that $B'$ has a cover of minimum order that contains $x$ and that is thereby also a cover of $B$. 

---

5
Lemma 4. Let $B$ be a tight bramble of a graph $G$ and let $S_1$ and $S_2$ be two covers of $B$. If $S \subseteq V(G)$ separates $S_1$ from $S_2$ in $G$, then $S$ is a cover of $B$.

Proof. Let $B$ be a tight bramble of a graph $G$ and $S_1, S_2$ two covers of $B$. Let $S \subseteq V(G)$ be a separator of $S_1$ and $S_2$. Consider a set $B \in B$ of the tight bramble. Since $S_1$ and $S_2$ cover $B$ and since $B$ is connected, there exists a path $P$ whose internal vertices belong to $B$ and whose endpoints belong to $S_1$ and $S_2$. Thus, since $S$ separates $S_1$ and $S_2$, there exists a vertex $x \in P$ such that $x \in S$ and thus, $S$ covers $B$. This holds for every $B \in B$, thus $S$ is a cover of $B$. $\square$

2.5 Mixed search games

In this paper, we deal with mixed search games on a graph $G$ introduced by Bienstock and Seymour [4]. The opponents are a team of searchers and a fugitive. We assume that both players have full knowledge of the graph and the position of their opponent in the graph. Moreover, the fugitive is agile in the sense that it may move at any moment though unguarded pathways. At each round, the searchers occupy a subset of vertices, called searchers’ position, while the fugitive is located on an edge, called fugitive location. A play is a (finite or infinite) sequence alternating between searchers’ positions and fugitive locations, that is, a sequence $P = (S_0, e_1, S_1, \ldots, e_t, S_t, \ldots)$ with $S_0 = \emptyset$ and where for $i \geq 1$, $S_i \subseteq V(G)$ is a searchers’ position and $e_i \in E(G)$ is a fugitive location. In case a play is finite, it always ends with the special symbol $\star$, replacing a fugitive location and indicating the fact that the fugitive has been captured. The cost of a play $P$ is the maximum size of a searchers’ position $S_i$ in it and is denoted by $\text{cost}(P)$.

The search strategy. A searchers’ move is a pair $(S, S') \in (2^{V(G)})^2$ indicating a transition from the searchers’ position $S$ to searcher’s position $S'$. In a mixed search game, a searchers’ move is legitimate if $|S \ominus S'| \in \{1, 2\}$ and, moreover, if $|S \ominus S'| = 2$ then $S \ominus S'$ is an edge of $G$. This allows three types of moves:

- [Placement of a searcher]: $S' = S \cup \{x\}$ for some $x \in V(G) \setminus S$. This type of move consists in placing a new searcher on vertex $x$.
- [Removal of a searcher]: $S = S' \setminus \{x\}$ for some $x \in S$. This type of move consists in removing a searcher from vertex $x$.
- [Sliding of a searcher along an edge]: $S \ominus S' = \{x, y\}$ and $xy \in E(G)$. This type of move corresponds to sliding the searcher initially positioned at vertex $x$, along the edge $xy$, towards eventually occupying vertex $y$.

As the searchers know the exact fugitive location, they can use this information to determine their next positions. Therefore, we may define a (mixed) search strategy on $G$ as a function $s_G : (2^{V(G)})^2 \to (2^{V(G)} \times E(G))$ such that, for every $(S, e) \in 2^{V(G)} \times E(G)$, the pair $(S, s_G(S, e))$ is a legitimate searchers’ move. We denote by $S_G$ the set of all search strategies on $G$. Every legitimate searchers’ move $(S, S')$ immediately clears a set of edges defined as follows:

$$\text{clear}_G(S, S') := \begin{cases} \{xy \mid x \in S\} \cap E(G), & \text{if } S' \setminus S = \{y\} \\ \emptyset, & \text{if } S' \setminus S = \emptyset. \end{cases}$$

The fugitive strategy. To formally define the fugitive strategy we need to introduce some concepts. Let us consider a legitimate searchers’ move $(S, S')$.

A pathway $W = (f_1, f_2, \ldots, f_t)$ of $G$, with $t \geq 2$, is $(S, S')$-avoiding if the following conditions are satisfied:

1. for every $j \in [2, t]$, $f_{j-1} \cap f_j \notin S \cap S'$, and
2. if $S' \setminus \{y\} = S \setminus \{x\}$ (that is, $(S, S')$ is a sliding move from $x$ to $y$ along the edge $xy$, see Figure 4), and $xy \in W$, then
Figure 4: Two legitimate moves \((S, S')\) and \((S, S')\)-avoiding pathway \(\mathcal{W} = \langle f_1, f_2, \ldots, f_t \rangle\) are depicted. On the left, we have \(S' = S \cup \{x\}\), and \(\mathcal{W}\) may go through the vertex \(x\). On the right, \(S \cap S' = \{x, y\}\), i.e., a searcher slides along the edge \(f_1 = xy\) from \(x\) to \(y\). Observe that, if \(t > 2\), then the edge \(f_t\) may be the edge \(f_1\).

Given a legitimate searchers’ move \((S, S')\) and an edge \(e\), the subset of edges of \(E(G)\) that are accessible from \(e\) through a \((S, S')\)-avoiding pathway of \(G\) is defined as

\[ A_G(S, e, S') := \{ e' \in E(G) \setminus (S' \setminus S) \mid \text{there is an } (S, S')\text{-avoiding } (e, e')\text{-pathway} \}. \]

We can now define the fugitive space so as to contain the edges where the fugitive initially residing at \(e\) may move after the searchers’ move \((S, S')\), that is

\[ \text{fsp}_G(S, e, S') := (\{ e \} \setminus \text{clear}_G(S, S')) \cup A_G(S, e, S'). \]

Given a graph \(G\), we set \(E^*(G) = E(G) \cup \{ \star \} \) and we define a fugitive strategy on \(G\) as a pair \((e_1, f_G) \in E(G) \times (E^*(G) \setminus E(G) \times 2^{\mathcal{V}(G)})\) such that, for the function \(f_G\), if \(\text{fsp}_G(S, e, S') \neq \emptyset\), then \(f_G(S, e, S') \in \text{fsp}_G(S, e, S')\), otherwise \(f_G(S, e, S') = \star\). We denote by \(\mathcal{F}_G\) the set if all fugitive strategies on \(G\).

**Winning and monotone search strategies** A search program (on a graph \(G\)) is a pair \((s_G, (e_1, f_G)) \in S_G \times \mathcal{F}_G\). Every search program \((s_G, (e_1, f_G))\) generates a play, denoted

\[ \mathcal{P}(s_G, e_1, f_G) := \langle S_0, e_1, S_1, \ldots, e_i, S_i, \ldots \rangle \]  

where for each \(i \geq 1\), \(S_i = s_G(S_{i-1}, e_i)\) and \(e_{i+1} = f_G(S_{i-1}, e_i, S_i)\). The search program \((s_G, e_1, f_G)\) is monotone if, in \(1\), for every \(i \geq 1\), the edge \(e_i\) has not been cleared at any step prior to \(i\), that is for every \(j \leq i\), \(e_i \notin \text{clear}_G(S_{j-1}, S_j)\). A search strategy \(s_G \in S_G\) is monotone if for every fugitive strategy \((e_1, f_G) \in F_G\), the program \((s_G, (e_1, f_G))\) is monotone.

Let \(s_G\) be a search strategy. The cost, denoted by \(\text{cost}(s_G)\), of \(s_G\) is the maximum cost of \(\mathcal{P}(s_G, e_1, f_G)\), over all \((e_1, f_G) \in \mathcal{F}_G\). Also, \(s_G\) is winning if for every fugitive strategy \((e_1, f_G) \in \mathcal{F}_G\), the play \(\mathcal{P}(s_G, e_1, f_G)\) is finite.

We define the mixed search number (against an agile and visible fugitive) of \(G\) as:

\[ \text{avms}(G) = \min \{ \text{cost}(s_G) \mid s_G \text{ is a winning search strategy in } S_G \}. \]

And if we restrict the search strategies to the monotone ones, we define:

\[ \text{mavms}(G) = \min \{ \text{cost}(s_G) \mid s_G \text{ is a monotone winning search strategy in } S_G \}. \]
3 Monotonicity of the mixed search game against an agile and visible fugitive

This section is devoted to the main result of this paper, that is Theorem 1 below. It provides a min-max characterization of graphs with Cartesian tree product number at most \(k\) in terms of tight bramble obstacles. Moreover, it shows that the Cartesian tree product number corresponds to the number of searchers required to capture an agile and visible fugitive in a mixed search game. As a byproduct, it proves that the mixed search game against an agile and visible fugitive is monotone. This results can be seen as the “visible counterpart” of the result of Bienstock and Seymour [4] where the monotonicity is proved for the case of an agile and invisible fugitive. Also, it can be seen as the “mixed counterpart” of the result of Seymour and Thomas [19] where the monotonicity is proved for the node search game against an agile and visible fugitive.

**Theorem 1.** Let \(G\) be a graph and \(k \geq 1\) be an integer. Then the following conditions are equivalent:

1. \(G\) has a loose tree-decomposition of width \(k\);
2. \(G\) is a minor of \(T^{(k)} = T \square K_k\) (i.e. \(\text{ctp}(G) \leq k\));
3. every tight bramble \(B\) of \(G\) has order at most \(k\);
4. the mixed search number against an agile and visible fugitive is at most \(k\) (i.e. \(\text{avms}(G) \leq k\));
5. the monotone mixed search number against an agile and visible fugitive is at most \(k\) (i.e. \(\text{mavms}(G) \leq k\)).

The proof of Theorem 1 is as follows. First, Lemma 6 proves that \((1 \iff 2)\). Then Lemma 8 establishes \((3 \Rightarrow 2)\). In turn Lemma 10 shows \((2 \Rightarrow 5)\). The fact that \((5 \Rightarrow 4)\) is trivial. Finally, we can conclude, using Lemma 9, that \((4 \Rightarrow 3)\).

3.1 The Cartesian tree product number and loose-tree decomposition

Lemma 6 establishes that the minimum width of a loose tree-decomposition is equal to the Cartesian tree product number of a graph \((1 \iff 2)\) from Theorem 1. We first show that every minor of \(T^{(k)} = T \square K_k\) admits a loose tree-decomposition of width \(k\). To that aim, we prove that the width of a loose tree-decomposition of a graph is a parameter that is closed under the minor relation (Lemma 5). Then, we build for \(T^{(k)}\) a loose tree-decomposition of width at most \(k\). To prove the reverse direction, we show that given a loose tree-decomposition \(D\) of width \(k\) of \(G\), one can complete the graph \(G\) into a graph \(H\) which is contained in \(T^{(k)}\) as a minor. The graph \(H\) is obtained by adding all possible missing edge between pair of vertices of the same bag of \(D\) and all possible missing marginal edges of \(D\).

**Lemma 5.** Let \(G\) and \(H\) be two graphs such that \(H \preceq G\). If \(G\) has a loose tree-decomposition of width \(k\), then also does \(H\).

**Proof.** Let \(D = (T, \chi)\) be a loose tree-decomposition of \(G\). Suppose that \(H\) is obtained by removing an edge or a vertex from a graph \(G\). It is clear from Definition 2 that restricting the bags of \(D\) to the vertices of \(H\) yields a loose tree-decomposition of \(H\) and does not increase the width. So suppose that \(H = G_{e}\) from some edge \(e = xy \in E(G)\). Let \(v_e\) be the new vertex resulting from the contraction of \(e\). We define \(D' = (T', \chi')\) such that for every \(t \in V(T)\), if \(x, y \notin \chi(t)\), then \(\chi'(t) = \chi(t)\), otherwise \(\chi'(t) = \chi(t) \setminus \{x, y\} \cup \{v_e\}\). We prove that \(D'\) is a loose tree-decomposition of \(H\).

- First observe that by condition (L2), in \(D\) the trace \(T_x\) of \(x\) and the trace \(T_y\) of \(y\) either intersect or are joined by a tree edge. It follows that in \(D'\), the trace \(T_{v_e}\) is connected. So condition (L1) holds for \(D'\).
- By construction of \(D'\), for every node \(t \in V(T)\) such that \(x \in \chi(t)\) or \(y \in \chi(t)\), we have \(v_e \in \chi'(t)\). This implies that \(D'\) satisfies condition (L2).
• Suppose that in $\mathcal{D}'$, the edge $uv \in E(H)$ is a marginal edge for the nodes $t_1$ and $t_2$ of $T$. This means that $u \in \chi'(t_1) \setminus \chi'(t_2)$ and $v \in \chi'(t_2) \setminus \chi'(t_1)$. By construction, if $u$ and $v$ both belong to $V(G)$, then $uv$ is also a marginal edge of $G$ for the nodes $t_1$ and $t_2$ in $\mathcal{D}$. So assume, without loss of generality that say $u = v_e$. As $v_e$ results from the contraction of the edge $xy \in E(G)$, $G$ contains the edge $xv$ or $yv$. Suppose that $xv \in E$. By construction of $\mathcal{D}'$, we have $x \in \chi(t_1) \setminus \chi(t_2)$. It follows that in $\mathcal{D}$, $xv$ is a marginal edge between the nodes $t_1$ and $t_2$ of $T$. So we proved that every marginal edge in $\mathcal{D}'$ corresponds to a marginal edge in $\mathcal{D}$. This implies that if for some tree-edge $t_1t_2$ of $T$, $\mathcal{D}'$ does not satisfies condition (L3), neither does $\mathcal{D}$.

Finally, we observe that, by construction, $\text{width}(\mathcal{D}, H) \leq \text{width}(\mathcal{D}, G)$, concluding the proof.  

\begin{lemma}
For every graph $G$, we have
\[ \text{ctp}(G) = \min \{ \text{width}(\mathcal{D}, G) \mid \mathcal{D} \text{ is a loose tree-decomposition of } G \}. \]
\end{lemma}

\begin{proof}
We first prove that $\min \{ \text{width}(\mathcal{D}, G) \mid \mathcal{D} \text{ is a loose tree-decomposition of } G \} \leq \text{ctp}(G)$. By Lemma 5, it is enough to prove the statement for $T^{(k)}$, where $k = \text{ctp}(G)$. Recall that, by construction of $T^{(k)}$, we have that $V(T^{(k)}) = \{ x(t,i) \mid t \in V(T), i \in [k] \}$ and $E(T^{(k)}) = \{ x(t,i)x(t,j) \mid t \in V(T), i \neq j \} \cup \{ x(t,j)x(t',j) \mid t, t' \in V(T), t \neq t', i \in [k] \}$. We build a loose tree-decomposition $\mathcal{D} = (T', \chi)$ of $T^{(k)}$ as follows:

• For the sake of the contraction of $T'$, we fix an arbitrary node $r$ of $T$ as the root of $T$, implying that for every node $t \in V(T)$ distinct from $r$, there is a uniquely defined parent node $p(t)$. The tree $T'$ is obtained from $T$ by every node $k - 1$ times. More formally, we define (see Figure 5):

\[ V(T') = \{ v(r,k) \} \cup \{ v(t,j) \mid t \in V(T), t \neq r, j \in [k] \}, \]

\[ E(T') = \{ v(t,j)v(t,j+1) \mid t \in V(T), t \neq r, j \in [k-1] \} \cup \{ v(p(t),k)v(t,1) \mid t \in V(T), t \neq r \}. \]

• We set $\chi(v(r,k)) = \{ x(c,i) \mid i \in [k] \}$ and for every node $v(t,j) \in V(T')$ such that $t \neq r$, we set $\chi(v(t,j)) = \{ x(t,j') \mid 1 \leq j' \leq j \} \cup \{ x(p(t),j') \mid j < j' \leq k \}$.

\begin{figure}[h]
\centering
\includegraphics[width=\textwidth]{figure5.png}
\caption{A loose tree-decomposition $\mathcal{D} = (T', \chi)$ of $T^{(3)} = T \boxdot K_3$. To build $\mathcal{D}$, we set node $a$ as the root of $T$. In blue, we have the trace $T'_{x(a,3)}$ and in red the trace $T'_{x(c,3)}$. The dashed red edges are the marginal edges of $\mathcal{D}$.}
\end{figure}

One can observe that by construction of $\mathcal{D}$, the trace $T'_{x(t,0)}$ of every vertex is connected. Therefore condition (L1) of Definition 2 holds. We observe that $T^{(k)}$ contains two types of edges. For an edge
\text{Let } e = x_{(t,i)}x_{(t,i')} \text{ for some node } t \in V(T) \text{ and some distinct integers } i, i' \in [k], \text{ or } e = x_{(t,i)}x_{(p(t),i)} \text{ where } t \in V(T) \text{ is not the root node and } i \in [k]. \text{ In the former case, } x_{(t,i)} \text{ and } x_{(t,i')} \text{ both belong to the bag } \chi(t,i,k). \text{ In the latter case, we observe that: 1) if } i = 1, \text{ then } x_{(t,i)} \in \chi(t,i) \text{ and } x_{(p(t),i)} \in \chi(v_{p(t),k}); 2) otherwise } x_{(t,i)} \in \chi(v_{(t,i)}k) \text{ and } x_{(p(t),i)} \in \chi(v_{(t,i)}-1)k. \text{ It follows that condition } (L2) \text{ of Definition 2 holds. Finally, observe that only the edges of } T(k) \text{ of the second type are not covered by a single bag. These are the marginal edges and by construction, there is at most one marginal edge between two adjacent nodes in } D. \text{ It follows that condition } (L3) \text{ of Definition 2 also holds and thereby } D \text{ is a loose tree-decomposition of } T(k). \text{ Finally, notice that } \text{width}(D, T(k)) = k, \text{ proving that } \min \{ \text{width}(D, T(k)) \mid D \text{ is a loose tree-decomposition of } T(k) \} \leq \text{ctp}(T(k)).$

Let us now prove that \text{ctp}(G) \leq \min \{ \text{width}(D, G) \mid D \text{ is a loose tree-decomposition of } G \}. \text{ By Lemma 1, we can assume that } D = (T, \chi) \text{ is a full loose tree-decomposition of } G \text{ such that } \text{width}(D, G) = k. \text{ We prove that } G \preceq T(k). \text{ Based on } D, \text{ we construct a graph } H \text{ by adding edges to } G \text{ as follows:}

\[ E(H) = \{ xy \mid \exists t \in V(T), \{ x, y \} \subseteq \chi(t) \} \cup \{ xy \mid \exists t,t' \in E(T), x \in \chi(t_1) \setminus \chi(t_2), y \in \chi(t_2) \setminus \chi(t_1) \} \]

That is the edge set of \text{H} contains all possible edges between vertices belonging to a common bag of \text{D} and all possible marginal edges between adjacent bags. Clearly \text{E(H)} contains \text{E(G)}. \text{ So, let us prove that } H \preceq T(k). \text{ To that aim, we iteratively build a minor-model } \rho \text{ of } H \text{ in } T(k) \text{ with the following algorithm.}

Initially, we set } \rho(x) = \emptyset \text{ for every vertex } x \in V(H). \text{ We guarantee that, at each step of the algorithm, if } x_{(t,i)} \in \rho(x) \text{ and } x_{(t,j)} \in \rho(x), \text{ then } i = j. \text{ We pick an arbitrary node } t \in V(T). \text{ For every } x \in \chi(t), \text{ we set } \rho(x) = \{ x_{(t,i)} \} \text{ (with } i \in [k]) \text{ in a way that, for } y \in \chi(t), \text{ if } x \neq y, \rho(x) \neq \rho(y). \text{ Set } S = \{ t \} \text{ as the set of processed nodes of } T \text{ (a node } t \text{ is processed when for every vertex } x \in \chi(t), \rho(x) \text{ is defined).}

Assume there exists an unprocessed node } t \notin S. \text{ We pick a node } t' \notin S \text{ having an adjacent node } t \in S. \text{ Suppose that } x \in \chi(t) \cap \chi(t'). \text{ Then } \rho(x) \text{ contains a vertex } x_{(t,i)} \text{ for some } i \in [k]. \text{ We add } x_{(t,i)} \text{ to } \rho(x). \text{ Otherwise, suppose that } x \in \chi(t') \setminus \chi(t). \text{ As } |\chi(t) \cap \chi(t')| = k - 1, \text{ there is a unique vertex } y \in \chi(t) \setminus \chi(t'). \text{ Let } j \in [k] \text{ be such that } x_{(t,j)} \in \rho(y). \text{ Then we add } x_{(t,j)} \text{ to } \rho(x).

First observe that by construction, for every \text{xy} \in V(H), \text{ the set } \rho(x) \text{ is a connected subset of } T(k). \text{ Let us argue that for every } xy \in E(H), T(k) \text{ contains an edge between a vertex of } \rho(x) \text{ and a vertex of } \rho(y). \text{ As explained in the description of } H, E(H) \text{ contains two type of edges } xy: \text{ either } V(T) \text{ contains a node } t \text{ such that } xy \subseteq \chi(t) \text{ or } xy \text{ is a marginal edge, that is } E(T) \text{ contains a tree-edge } t_1, t_2 \text{ such that } x \in \chi(t_1) \setminus \chi(t_2) \text{ and } y \in \chi(t_2) \setminus \chi(t_1). \text{ In the former case, by the construction of } \rho(x), \text{ there exist distinct } i, i' \in [k] \text{ such that } x_{(t,i)} \in \rho(x) \text{ and } x_{(t,i')} \in \rho(y). \text{ Observe that by definition of } T(k), x_{(t,i)}x_{(t,i')} \in E(T(k)). \text{ In the latter case, there exist in } T \text{ two adjacent nodes } t_1 \text{ and } t_2 \text{ such that } x \in \chi(t_1) \setminus \chi(t_2), y \in \chi(t_2) \setminus \chi(t_1). \text{ Again, by the construction of } \rho(x) \text{ and } \rho(y), \text{ there exists a unique } i \in [k] \text{ such that } x_{(t,i)} \in \rho(x) \text{ and } x_{(t,i)} \in \rho(y). \text{ Observe that } x_{(t,i)}x_{(t,i)} \in E(T(k)). \text{ It follows that } \rho \text{ certifies that } H \text{ is a minor of } T(k). \text{ As } G \text{ is a subgraph of } H, G \text{ is a minor of } T(k) \text{ and thereby } \text{ctp}(G) \leq k. \qed

3.2 Tight brambles certify large Cartesian tree product number

In this subsection, we show \text{Lemma 8} that the existence of tight bramble of order } k \text{ in a graph } G \text{ certifies the fact that the Cartesian tree product number of } G \text{ is at most } k \text{ ((3 }\Rightarrow\text{ 2) of Theorem 1). Our proof follows the lines of the proof of Bellenbaum and Diestel 2 where it is shown that, in the context of treewidth, a bramble of large order is an obstacle to a small treewidth. We first prove a technical lemma showing that extending in a connected way the trace } T_x \text{ of a vertex } x \text{ in a loose tree-decomposition } D = (T, \chi) \text{ of a graph } G \text{ yields another loose tree-decomposition of } G.

\text{Lemma 7. Let } D = (T, \chi) \text{ be a loose tree-decomposition of a graph } G. \text{ Let } \chi' : V(T) \rightarrow 2^{V(G)} \text{ be such that for every } x \in V(G), \{ t \in V(T) \mid x \in \chi'(t) \} \text{ induces a connected subtree } T'_x \text{ of } T \text{ and the trace } T_x \text{ is a subtree of } T'_x, \text{ then } D' = (T, \chi') \text{ is a loose tree-decomposition of } G.

\text{Proof. Let us show that the conditions } (L1), (L2) \text{ and } (L3) \text{ of Definition 2 are satisfied by } D'. \text{ Clearly, } (L1) \text{ is verified by definition of } T'_x. \text{ Suppose } xy \text{ is an edge in } E(G). \text{ As } D \text{ is a loose tree-decomposition,
there exists a tree-edge $f = t_1 t_2 \in E(T)$ such that $xy \in E\bigl(G[\chi(t_1) \cup \chi(t_2)]\bigr)$. As for every vertex $x$, $T_x$ is a subtree of $T'_x$, we have $xy \in E\bigl(G[\chi(t_1) \cup \chi(t_2)]\bigr)$. It follows that (L2) holds. Finally, observe that as, by construction of $D'$, for every vertex $x$, the trace $T'_x$ is a subtree of $T'_x$, every marginal edge in $D'$ is a marginal edge in $D$, implying that $D'$ satisfies (L3). \hfill \Box

Given a tight bramble $B$ of a graph $G$ of order at most $k$, a loose tree-decomposition $D = (T, \chi)$ of $G$ is $B$-admissible if for every node $t \in V(T)$ such that $|\chi(t)| > k$, the bag $\chi(t)$ fails to cover $B$.

**Lemma 8.** Let $G$ be a graph and $k \geq 1$ be an integer. If the maximum order of a tight bramble of $G$ is $k$, then $\text{ctp}(G) \leq k$.

**Proof.** We prove that if $G$ does not contain a tight bramble of order $k + 1$ or larger, then for every tight bramble $B$ of $G$, there exists a $B$-admissible loose tree-decomposition of $G$. This statement implies $\text{ctp}(G) \leq k$. Indeed, $B = \emptyset$ is a tight bramble. As every subset of vertices covers the empty bramble, a $\emptyset$-admissible loose tree-decomposition cannot contain a bag of size larger than $k$. It follows by Lemma 6 that $\text{ctp}(G) \leq k$.

Let $B$ be a non-empty tight bramble of $G$ and let $X$ be a cover of $B$ of minimum size. We proceed by induction on the size of $B$.

For the induction base, suppose that the size of $B$ is maximum. Let $\text{cc}(G - X)$ be the set of connected components of $G - X$. We build a $B$-admissible loose tree-decomposition $D = (T, \chi)$ of $G$ as follows. The tree $T$ is a star with $|\text{cc}(G - X)|$ leaves. More precisely, we have $V(T) = \{x\} \cup \{t_C \mid C \in \text{cc}(G - X)\}$ and $E(T) = \{x t_C \mid C \in \text{cc}(G - X)\}$. We set $\chi(x) = X$. It remains to define the bag $\chi(t_C)$ for every connected component $C \in \text{cc}(G - X)$. Observe that since $C \cap X = \emptyset$ and since $X$ is a cover of $B$, $C \notin B$. Moreover, as $B$ has maximum size, $B \cup \{\{C\}\}$ is not a tight bramble of $G$. This implies that $B$ contains a set $B$ such that $B$ and $C$ do not touch. It follows that $B \cap C = \emptyset$ and $C$ contains at most one edge $uv$ such that $u \in B \setminus C$ and $v \in C \setminus B$. If such an edge $uv$ exists, then we set $\chi(t_C) = (C \cup N_G(C)) \setminus \{u\}$. Otherwise, we set $\chi(t_C) = C \cup N_G(C)$. In both cases, we have $\chi(t_C) \cap B = \emptyset$ and henceforth $\chi(t_C)$ does not cover $B$. So if $D = (T, \chi)$ is a loose tree-decomposition of $G$, then it is a $B$-admissible one. Let us prove that the three conditions of Definition 2 are satisfied. Condition (L1) follows from the fact that if a vertex $x$ of $G$ belongs to several bags, then it belongs to $\chi(t_X)$. Condition (L2) holds as $\chi(t_X)$ is a separator and for every connected component $C \in \text{cc}(G - X)$, $\chi(t_C) \subseteq X \cup C$. Finally, condition (L3) is also satisfied because, by construction, if there exists a marginal edge between node $t_X$ and node $t_C$, then it is unique (as otherwise the sets $C$ and $B$ would touch).

We now consider the case where the size of $B$ is not maximum. By induction hypothesis, suppose that the statement holds for every tight bramble $B'$ containing more elements than $B$. We also assume that for every such larger tight bramble $B'$, none of the $B'$-admissible loose tree-decompositions is also $B$-admissible, as otherwise we are done. Observe that we can assume that $V(G)$ is not a minimum cover of $B$, as otherwise $|V(G)| \leq k$ and thereby the loose tree-decomposition containing a unique bag $V(G)$ would be $B$-admissible. By Lemma 6, we then have $\text{ctp}(G) \leq k$. So we assume that $X \neq V(G)$. For a set $S \subseteq V(G)$, we say that a loose tree-decomposition $D = (T, \chi)$ of $G$ is $S$-rooted if $T$ contains a node $t$ such that $S \subseteq \chi(t)$.

**Claim 1.** For every connected component $C$ of $G - X$, there exists a $X$-rooted loose tree-decomposition $D_C = (T_C, \chi_C)$ of $H = G[C \cup X]$ such that for every node $t \in V(T_C)$ such that $|\chi_C(t)| \geq k + 1$, $\chi(t)$ does not cover $B$.

Suppose Claim 1 holds. Since for every $C \in \text{cc}(G - X)$, $D_C = (T_C, \chi_C)$ contains a node $t_C$ such that $X \subseteq \chi_C(t_C)$, these loose tree-decompositions can be amalgamated into a loose tree-decomposition $D = (T, \chi)$ of $G$ as follows: $T$ contains a node $t_X$ such that $\chi(t_X) = X$ and for each $C \in \text{cc}(G - X)$, $t_X$ is made adjacent to the node $t_C$ of $T_C$.

**Proof of Claim 1.** Let $C$ be a connected component of $G - X$. We denote $H = G[X \cup C]$ and consider $B' = B \cup \{C\}$. We consider two cases:

- The set $B'$ is not a tight bramble of $G$. Then $B$ contains a set $B$ such that $B$ and $C$ are not touching, that is $B \cap C = \emptyset$ and $E(G)$ contains at most one edge $e$ that is incident to a vertex of $B$ and to a

11
vertex of $C$. We proceed as in the induction base case above. Consider $D_C = (T_C, \chi_C)$ where $T_C$ is the tree defined on two nodes $t_1$ and $t_2$. We set $\chi_C(t_1) = X$. If there is an edge $uv$ such that $u \in B \setminus C$ and $v \in C \setminus B$, then $\chi_C(t_2) = (C \cup N_G(C)) \setminus \{u\}$, otherwise $\chi_C(t_2) = C \cup N_G(C)$. First observe that $D_C$ is a loose tree-decomposition of $H$ satisfying the statement of the claim. Indeed, by construction, as $B$ and $C$ are not touching. It follows that on the one hand, there is at most one marginal edge between $\chi(t_1)$ and $\chi(t_2)$, and so $D_C = (T_C, \chi_C)$ is a loose tree-decomposition of $H$. On the other hand, this implies that $B \cap C = \emptyset$ and so $\chi(t_C)$ does not cover $B$.

- The set $B'$ is a tight bramble of $G$. Since $X$ covers $B$ and $C \cap X = \emptyset$, $C \notin B$. Therefore, we have $|B'| > |B|$. Consequently, by the induction hypothesis, we can assume the existence of a $B'$-admissible loose tree-decomposition $D = (T, \chi)$ of $G$. By the induction assumption, $D$ is not $B$-admissible. This implies that there exists a node $s \in V(T)$ such that $|\chi(s)| \geq k + 1$ and $\chi(s)$ covers $B$. We build from $D$ a $X$-rooted loose tree-decomposition $D_C = (T_C, \chi_C)$ of $H = G[X \cup C]$ as follows (see Figure 6), for every vertex $x \in X$, let $t_x \in V(T)$ be the node of $T_x$ that is the closest to $s$ in $T$. For every node $t \in V(T)$, we set:

$$\chi_C(t) = (\chi(t) \cap V(H)) \cup \{x \in X \mid t \text{ belongs to the unique } (t_x, s)\text{-path in } T\}.$$ 

![Figure 6](image)

Figure 6: Suppose that $X = \{a, b, c, d\}$ and that node $s$ has size $|\chi(s)| > k$. The nodes $t_a, t_b, t_c$ and $t_d$ are respectively the nodes of the traces $T_a, T_b, T_c$ and $T_d$ that are the closest to $s$. To construct $D_C$, vertices $a, b, c$ and $d$ are respectively added to the the bag on the paths between $s$ and $t_a, t_b, t_c$ and $t_d$.

Finally $T_C$ is obtained by restricting $T$ to the nodes $V(T_C) = \{t \in V(T) \mid \chi_C(t) \neq \emptyset\}$. Observe that by construction of $\chi_C$, for every vertex $x \in X \cup C$, the set $T_{C,x} = \{t \in V(T_C) \mid x \in \chi_C(t)\}$ contains the trace $T_x$ of $x$ in $D$ and the unique path in $T$ between the trace $T_x$ and the node $s$. It follows that $T_{C,x}$ is a connected subtree of $T$ and so Lemma 7 applies. Consequently $D_C = (T_C, \chi_C)$ of $H = G[X \cup C]$ is a loose tree-decomposition of $H$.

We now prove that $D_C$ satisfies the statement of the claim. To that aim, we first prove that for every node $t \in V(T_C)$, $|\chi_C(t)| \leq |\chi(t)|$. As $\chi(s)$ and $X$ both cover the tight bramble $B$, by Lemma 4 any separator between $X$ and $\chi(s)$ also covers $B$. By the minimality of $|X|$, such a separator has size at least $|X|$. It follows by Menger Theorem that there exists a set $P$ of $|X|$ vertex disjoint paths between $X$ and $\chi(s)$. For every $x \in X$, we denote by $P_x$ the path of $P$ containing $x$. As $(T, \chi)$ is $B'$-admissible and $|\chi(s)| \geq k + 1$, $\chi(s)$ fails to cover $B'$. Since $\chi(s)$ covers $B$ and since $B' = B \cup \{C\}$, it follows that $\chi(s)$ does not intersect $C$. It follows that every path $P_x \in P$ belongs to $G - C$ (see Figure 7). Let us now consider a node $t$ for which there exists a vertex $x \in \chi_C(t) \setminus \chi(t)$. Observe that $t$ lies in $T_C$ on the unique $(t_x, s)$-path. By Lemma 2 $\chi(t)$ separates $\chi(t_x)$ and $\chi(s)$. It follows that $\chi(t)$ contains a vertex of $P_x$. As $P_x$ is a path of $G - C$, for every vertex $x \in \chi_C(t) \setminus \chi(t)$, we identify a vertex $y \in \chi(t) \setminus \chi_C(t)$. It follows that $|\chi(t)| \leq |\chi(t)|$.

To conclude, let $t \in V(T_C)$ be a node such that $|\chi_C(t)| > k$. Since $|X| \leq k$ and since $\chi_C(t) \subseteq X \cup C$, we have that $\chi_C(t) \cap C \neq \emptyset$. As $(T, \chi)$ is $B'$-admissible, $\chi(t)$ does not intersect some $B \in B$. Let us
Figure 7: The set $\chi(s)$ is disjoint from $C$ and $|X| \leq \chi(s)$. The paths $P_a$, $P_b$, $P_c$ and $P_d$ are pairwise vertex disjoint and do not intersect the component $C$.

show that $\chi_C(t)$ does not intersect $B$ either. Assume it does. Then there exists $x \in B$ such that $x \in \chi_C(t) \setminus \chi(t)$. Observe that by construction of $\chi_C(t)$, $x \in X$ and thereby $\chi(x) \cap B \neq \emptyset$. As $\chi(s)$ covers $B$, we also have that $\chi(s) \cap B \neq \emptyset$. By Lemma 2, $\chi(t)$ separates $\chi(s)$ and $\chi(t')$. Since $B$ is a connected subset of vertices, $\chi(t) \cap B \neq \emptyset$, a contradiction. Finally, as by construction every vertex of $X$ belongs to $\chi_C(s)$, $D_C$ is $X$-rooted. The claim follows.

3.3 Escape strategies derived from tight brambles

We now show how given a tight bramble of order $k$ in a graph $G$, a fugitive can derive an escape strategy $(e_1, f_G) \in F_G$ such that for every search strategy $s_G \in S_G$ of cost $k$, the play $P(s_G, e_1, f_G)$ generated by the program $(s_G, (e_1, f_G))$ is infinite. In other words, the fugitive cannot be captured by a set of $k$ searchers. This proves (4 $\Rightarrow$ 3) from Theorem 1.

Lemma 9. Let $G$ be a graph and $k \geq 1$ be an integer. If $G$ has a tight bramble of order $k$, then avms$(G) \geq k$.

Proof. Let us first consider the case $k = 1$. By Observation 1, trees are the connected graphs for which the maximum order of a tight bramble is 1. Observe that, in a tree $T$, one searcher is enough to capture the fugitive. Suppose that the unique searcher is located at vertex $x$ and that the fugitive is located at edge $e$. Then the search strategy consists in sliding along the unique edge $xy$ incident to $x$ towards $e$: that is, $s_T(x, e) = y$ where $y$ is the unique neighbor of $x$ in the connected component of $T - x$ containing $e$. Clearly, eventually the fugitive will be located on an edge incident to a leaf of $T$ and will be captured.

So let us consider $B$ a tight bramble of $G$ of order $k \geq 2$. Let $s_G \in S_G \subseteq (2^{V(G)})^{(2^{V(G)}) \times E(G)}$ be an arbitrary search strategy such that cost$(s_G) < k$. Let $B_0$ be an arbitrary tight bramble element and let $e_1$ be an edge of $E(B_0)$. We build a fugitive strategy $(e_1, f_G) \in F_G$ such that the play $P(s_G, e_1, f_G) = \langle s_G(e_1), f_G(S_{e_1-1}, e_1, S_{e_1}) \rangle$ generated by the program $(s_G, (e_1, f_G))$ verifies that for every $i \geq 1$, $f_G(S_{e_1-1}, e_1, S_{e_1}) \neq \emptyset$. Such a fugitive strategy $(e_1, f_G)$ certifies that the fugitive is never captured and thereby $s_G$ is not winning. To that aim, we show that for every $i \geq 1$, there exists $B_i \in B$ such that $S_i \cap B_i = \emptyset$ and $B_i \subseteq A_G(S_{e_1-1}, e_1, S_{e_1})$. This allows us to select $e_{i+1} = f_G(S_{e_1-1}, e_1, S_{e_1}) \in B_i$.

We proceed by induction on $i$. Clearly, since $k \geq 2$, the property is satisfied for $i = 1$. Indeed, as $S_0 = \emptyset$, we have that $|S_1| = 1$. Thereby $S_1$ is not a cover of $B$. So there exists $B_1 \in B$ which is disjoint from $S_1$. Suppose that $B_0 \neq B_1$ (otherwise, we are done). As $B_0$ and $B_1$ are touching connected subsets of vertices of $G$ and as $|S_1| = 1$, we have that $B_1 \in A_G(S_0, e_1, S_1)$. It follows that we can set $f_G(S_0, e_1, S_1) = e_2$ with $e_2$ being any edge of $E(B_1)$. Suppose that the property holds for every $j$ such that $1 \leq j < i$. We distinguish three cases:
• \( S_i = S_{i-1} \setminus \{u\} \) (that is, a searcher is removed from vertex \( u \)): It follows that \( S_i \cap B_{i-1} = \emptyset \) and thereby we can set \( B_i = B_{i-1} \) and \( f_G(S_{i-1}, e_i, S_i) = e_{i+1} \) with \( e_{i+1} \) being any edge of \( E(B_i) \). Observe that the fugitive may not move at such a step.

• \( S_i = S_{i-1} \cup \{v\} \) (that is, a new searcher is placed on vertex \( v \)): Observe that if \( v \notin B_{i-1} \), then \( B_{i-1} \cap S_i = \emptyset \). As \( e_i \in E(B_{i-1}) \) and \( B_{i-1} \) is connected, we also have that \( B_{i-1} \subseteq A_G(S_{i-1}, e_i, S_i) \). Thereby we can set \( B_i = B_{i-1} \) and \( f_G(S_{i-1}, e_i, S_i) = e_{i+1} \) with \( e_{i+1} \) being any edge of \( E(B_i) \). So assume that \( v \in B_{i-1} \). As \( |S_i| < k \), \( S_i \) is not a cover of \( B \) and there exists \( B_i \in B \) such that \( S_i \cap B_i = \emptyset \). Now observe that \( S_i \cap B_{i-1} = \{v\} \). It follows that as \( B_{i-1} \) and \( B_i \) are touching, every edge in \( E(B_i) \) is accessible through a \((S_{i-1}, S_i)\)-avoiding pathway from \( e_i \), that is \( B_i \subseteq A_G(S_{i-1}, e_i, S_i) \). Thereby we can set \( f_G(S_{i-1}, e_i, S_i) = e_{i+1} \) with \( e_{i+1} \) being any edge of \( E(B_i) \).

![Figure 8: Two consecutive sets \( S_{i-1} \) and \( S_i \) of vertices occupied by the searchers from the play \( \mathcal{P} \) such that \( S_i \cap S_{i-1} = \{u,v\} \) is an edge of multiplicity one. The tight ramble element \( B_{i-1} \in B \) that is disjoint from \( S_{i-1} \) contains the edge \( e_i \). Likewise the tight ramble element \( B_i \in B \) that is disjoint from \( S_i \) contains the edge \( e_{i+1} \). We observe that if \( B_{i-1} \) and \( B_i \) are disjoint, as they are touching, then there exists a pathway from \( e_i \) to \( e_{i+1} \) going through the edge \( xy \) that avoids the edge \( uv \).](image)

• \( S_i \cap S_{i-1} = \{u,v\} \) is an edge of \( E(G) \) (that is, a searcher slides on the edge \( uv \) towards \( v \)): As in the previous case, observe that if \( v \notin B_{i-1} \), then \( B_{i-1} \cap S_i = \emptyset \). As \( e_i \in E(B_{i-1}) \) and \( B_{i-1} \) is connected, we also have that \( B_{i-1} \subseteq A_G(S_{i-1}, e_i, S_i) \). Thereby we can set \( B_i = B_{i-1} \) and \( f_G(S_{i-1}, e_i, S_i) = e_{i+1} \) with \( e_{i+1} \) being any edge of \( E(B_i) \). So assume that \( v \in B_{i-1} \). As \( |S_i| < k \), \( S_i \) is not a cover of \( B \) implying the existence of \( B_i \in B \) such that \( S_i \cap B_i = \emptyset \) (and so \( v \notin B_i \)). If \( B_i \cap B_{i-1} \neq \emptyset \), then by the connectivity of the tight ramble elements, clearly every edge in \( E(B_i) \) is accessible through a \((S_{i-1}, S_i)\)-avoiding pathway from \( e_i \). Suppose that \( B_i \cap B_{i-1} = \emptyset \) (see Figure 8). As \( B_i \) and \( B_{i-1} \) are touching, there exists an edge \( xy \) distinct from \( \{u,v\} \) such that \( x \in B_i \) and \( y \in B_{i-1} \). Again, the connectivity of the tight ramble elements implies that every edge in \( E(B_i) \) is accessible through a \((S_{i-1}, S_i)\)-avoiding pathway from \( e_i \) containing the edge \( xy \). So in both cases, we have \( B_i \subseteq A_G(S_{i-1}, e_i, S_i) \). Thereby we can set \( f_G(S_{i-1}, e_i, S_i) = e_{i+1} \) with \( e_{i+1} \) being any edge of \( E(B_i) \).

\[ \square \]

### 3.4 Monotone search strategies derived from loose tree-decompositions

We show that a loose tree-decomposition of width \( k \) for a graph \( G \) can be used to design a winning search strategy \( s_G \in \mathcal{S}_G \) of cost \( k \) that is monotone. This establishes \((2 \Rightarrow 5)\) from Theorem 1.

**Lemma 10.** Let \( G \) be a graph and \( k \geq 0 \) be an integer. If \( \text{ctp}(G) \leq k \), then \( \text{mavms}(G) \leq k \).

**Proof.** Suppose that \( \text{ctp}(G) \leq k \). By **Lemma 6** \( G \) admits a full loose tree-decomposition \( \mathcal{D} = (T, \chi) \) such that \( \text{width}(\mathcal{D}) \leq k \). We build from \( \mathcal{D} \) a search strategy \( s_G \in \mathcal{S}_G \subseteq \{2^{\chi(T)}\} \) and prove that it is a winning strategy of cost at most \( k \). Consider an arbitrary fugitive strategy \( (e_1, f_G) \in \mathcal{F}_G \) and let \( \mathcal{P}(s_G, e_1, f_G) = (S_0, e_1, S_1, \ldots, S_{k-1}, e_k, S_k) \) be the play generated by the program \((s_G, e_1, f_G))\). For \( i \geq 1 \), the searchers’ position \( S_i = s_G(S_{i-1}, e_i) \) is defined as follows. At every step \( i \), we guarantee the existence of a node \( t \in V(T) \) such that \( S_i \subseteq \chi(t) \). Pick a vertex \( x \in V(G) \) and consider a node \( t \in V(T) \) such that \( x \in \chi(t) \). We set \( S_1 = \{x\} \) and for \( 1 < i \leq |\chi(t)| \), \( S_i = S_{i-1} \cup \{y\} \) for some

[14]
y ∈ χ(t) \ S_{i-1}. That is, up to step ℓ, we iteratively add a searcher on every vertex of χ(t). Suppose that i > ℓ. Let t = V(T) be the node such that S_{i-1} ⊆ χ(t) and let f = {t_1, t_2} be the tree-edge of T such that e_i = f_G(S_{i-2}, e_{i-1}, S_{i-1}) ∈ E(G[χ(t_1) ∪ χ(t_2)])). Suppose that t_1 is closer to t in T than t_2 is. Let t' be the neighbour of t in T such that t' and t_2 are in the same connected component of T - tt'. Observe that we may have t = t_1 and thereby t' = t_2. As D is full, there are u ∈ χ(t) and v ∈ χ(t') such that \{u, v\} = χ(t) ∩ χ(t'). There are two cases to consider:

1. if uv ∈ E(G), then S_i = s_G(S_{i-1}, e_i) = χ(t') is obtained by sliding along the edge uv (towards v);
2. if uv ∉ E(G), then S_i = s_G(S_{i-1}, e_i) = χ(t) \ \{u\} is obtained by removing a searcher from vertex u, and S_{i+1} = s_G(S_i, e_{i+1}) = χ(t'), with e_{i+1} = f_G(S_{i-1}, e_i, S_i), is obtained by adding a searcher on vertex v.

Let us prove that s_G is a winning search strategy. To that aim, we show that there is some step i ≥ 1 such that fsp_G(S_{i-1}, e_i, S_i) = ∅. First observe, that if at step i a searcher is added, that is S_i = S_{i-1} ∪ \{u\} for some u ∈ V(G), then fsp_G(S_{i-1}, e_i, S_i) ⊆ fsp_G(S_{i-2}, e_{i-1}, S_{i-1}). Now suppose that at step i, a searcher slides on the edge uv where \{u, v\} = χ(t) ∩ χ(t'). By Lemma 2, χ(t) is a separator of G. Observe that, by construction of s_G, either e_i = uv or e_i and v belong to the same component of G - χ(t). It follows that fsp_G(S_{i-1}, e_i, S_i) ⊆ fsp_G(S_{i-2}, e_{i-1}, S_{i-1}). Finally, suppose that at step i, a searcher is removed from a vertex u ∈ S_{i-1}. By construction of s_G, this is only the case where the set \{u, v\} = χ(t) ∩ χ(t') does not correspond to an edge of E(G). By Lemma 3, χ(t) ∩ χ(t') is a separator of G. Observe in that case that fsp_G(S_{i-1}, e_i, S_i) = fsp_G(S_{i-2}, e_{i-1}, S_{i-1}). But as, by construction, s_G does not contain two consecutive steps removing a searcher, we can conclude that there exists some step i such that fsp_G(S_{i-1}, e_i, S_i) = ∅.

Moreover observe that, from the discussion above, for every (e_1, f_1) ∈ F_G, the play generated by the program (s_G, (e_1, f_1)) is monotone. This, in turns, implies that the strategy s_G is monotone. Finally we observe that by the construction of s_G, we have cost(s_G) = ctp(G) ≤ k, proving the result.

4 Discussion

In this paper, we defined the concepts of loose tree-decomposition and tight bramble. We showed that the existence of a tight bramble of large order in a graph is an obstacle to a loose tree-decomposition of small width. Moreover, we proved the equivalence of the corresponding parameters to the Cartesian product number, introduced as the largeur d’arborescence by Colin de Verdière [22] (see also [19]) and the mixed search number against an agile and visible fugitive (Theorem 1).

One may consider path-like counterparts of all these concepts as follows. We can restrict the definition of loose tree-decomposition to path instead of tree, then we obtain loose path-decompositions. Similarly, if in the definition of Cartesian tree product number, we again consider trees instead of paths, this yields the definition of the Cartesian path product number. A “path analogue” of Theorem 1 may easily be produced by considering the mixed search number against an agile and invisible fugitive introduced by Bienstock and Seymour in [3], while the min-max analogue for these path-like parameters can be derived by the framework of [7]. Finally, we wish to mention that a different variant for path-decomposition that is equivalent the above parameters was introduced by Takahashi and Ueno and Kajitani in [21, 20] under the name proper path decomposition.

Finally, our results may support the belief that it might be possible to derive the min-max duality of Theorem 1 using general parameter duality frameworks such as those in [16, 13, 1, 14].

Acknowledgments. We would like to thank the anonymous referees for their careful reading and accurate remarks that helped us to greatly improve the presentation of the manuscript.
