(Received August 29, 1983)

Summary The present study was designed to determine the effect of purified viscous polysaccharides on pancreatic exocrine secretion and biliary output. Male Sprague-Dawley rats aged 5 weeks were fed either on the control diet which contained no fiber or on the experimental diets that contained 5% indigestible polysaccharides (agar, κ-carrageenan, Na-alginate and konjac mannan). After pretreatment with each diet for 2 weeks, the diet was discontinued overnight, and the animals were then allowed to eat 4g of the test diet in 1h. Immediately after this, a polyethylene tube was placed in the common bile duct, under anesthesia. Combined, free drained pancreatic-bile juice was collected for the following 1h.

Long-term (2 weeks) administration of Na-alginate and konjac mannan gave rise to increases in the volume of secreted juice and in the output of total bile acids, amylase and protease, whereas that of agar and κ-carrageenan had no affect. Since a single dose of Na-alginate and konjac mannan was ineffective as regards pancreatic-bile secretion, the elevated secretion observed over prolonged periods may result from processes of adaptation against highly viscous polysaccharides.

Key Words indigestible polysaccharides, agar, κ-carrageenan, Na-alginate, konjac mannan, pancreatic secretion, biliary output, viscosity

Dietary fibers are known to increase the fecal excretion of protein, fat and other nutrients (1, 2), which is probably due to the interference with digestion and absorption of food in the gut (3). In a previous paper, we reported that the digestive
organs responded with increased weight and length to oral administration of dietary fibers in experimental animals (4), and that some highly viscous indigestible polysaccharides such as Na-alginate, K-carrageenan, pectin and konjac mannan were able to affect the digestive function of rats. Sheard and Schneeman (5) observed that some dietary fibers led to an increase in pancreas weight and to stimulation of digestive enzyme secretion from the pancreas, although the latter response was shown with wheat bran and was indirectly determined.

This study was undertaken to determine the effect of viscous indigestible polysaccharides on pancreatic exocrine secretion and biliary output by an experimentally designed direct method.

METHODS

1. Animals. Weanling male Sprague-Dawley rats aged 5 weeks were used in all experiments. Rats were housed individually in stainless-steel wire-bottomed cages and kept at a constant temperature of 23 ± 1°C and a 12 h light-dark cycle.

2. Diet. A basal diet which consisted of casein 20%, soybean oil 10%, mineral mixture (AIN-76 (6)) 4.0%, vitamin mixture (AIN-76 (6)) 1.0%, choline bitartrate 0.15%, and sucrose up to 100% was used as the control non-fiber diet. Rats were fed on either the control diet or one of the four experimental diets in which an equal amount of sucrose at the 5% level was substituted with the following samples: agar (agar powder, Wako Pure Chemical Ind., Ltd.), K-carrageenan (Wako Pure Chemical Ind., Ltd.), Na-alginate (Wako Pure Chemical Ind., Ltd.) and konjac mannan (konjac flour rinsed with 50% ethyl alcohol several times).

3. Collection of pancreatic-biliary juice. Rats were maintained on each of the diets and water ad libitum for given periods, being fasted one night before the experiment. On the morning of the experiment, animals were allowed to eat 4 g of the same diet in 1 h. Anesthesia was given by an intraperitoneal administration of urethane at 130 mg/100 g body weight. The animals were then operated on and a pancreatic-bile cannulae of polyethylene tubing was inserted through the common bile duct near the duodenum. The secreted juice was free drained and collected for 1 h.

4. Analytical method. The volume of juice obtained was measured. Protein concentration and amylase activity in the juice was determined according to the methods of Lowry (7) and Fuwa (8) respectively. Protease activity was assayed by Anson’s method (9) using urea-denaturated hemoglobin as the substrate after activating with enterokinase prepared from the rat duodenal mucosa. Total bile acid content was assayed using 3α-hydroxysteroid dehydrogenase (10).

5. Statistics. Data obtained from 6 or 7 rats on each experimental diet were compared with the data from those on the control diet by using Student’s non-paired t-test.
Table 1. Body weight gain and food intake in rats on the control (no-fiber) and indigestible polysaccharide diets for two weeks. Two sets of experiments (Exp. 1 and Exp. 2) were conducted under the same experimental conditions.

RESULTS

1. Response of pancreatic-biliary secretion after two weeks of continuous administration of polysaccharides

Experiments 1 and 2 were performed separately under the same conditions to clarify the effect of seaweed polysaccharides and konjac mannan. Table 1 shows the results of averaged daily body weight gain and food consumption in rats fed on the control and indigestible polysaccharide diets for 2 weeks. All rats on the agar, \( \kappa \)-carrageenan or konjac mannan diet showed nearly the same body weight gain and food consumption as each control group of rats. However, the rats on Na-alginate diet showed significantly low values as compared to the control.

The pancreatic-biliary responses determined 2 weeks after the feeding of experimental diets are shown in Fig. 1. The animals fed Na-alginate showed increases in the volume of secreted juice and in the outputs of total bile acids.

Amylase and protease as compared to the control. The animals on konjac mannan in experiment 2 also responded with an elevated juice volume and amylase secretion and without any changes in the secretion of total bile acids and protease.

On the other hand, the two groups of animals fed agar and κ-carrageenan did not show any significant changes from the control in the pancreatic-bile secretion.

2. Response of pancreatic-bile secretion to single administration of Na-alginate or konjac mannan

As an enhanced pancreatic-bile response was obtained in the above experiments in which either Na-alginate or konjac mannan was given, another experiment was performed to see whether such a response could be induced immediately after single administration of those polysaccharides.

Figure 2 shows pancreatic-bile secretion following single administration of the control, Na-alginate or konjac mannan diets. All the rats used in this experiment were given the control diet for 2 weeks before the study. No enhanced secretory response to either Na-alginate or konjac mannan was observed when compared to the control.

3. Serial determinations on the responses to Na-alginate feeding

Table 2 shows the results obtained before and 3, 7 and 14 days after Na-

* Mean of 7 rats ± SE. * Significantly different from the control groups (p < 0.05).
alginate feeding. As expected, the animals on Na-alginate had suppressed body weight compared to the control animals. The volume of juice, amylase activity and total bile acids in the pancreatic-bile secretion were significantly more increased 7 days after the Na-alginate feeding than in the control group, whereas an increase in protease activity seemed to take more than 7 days. Administration of Na-alginate for 14 days brought about a more marked rise in the volume of juice and amylase activity, but did not further increase the secretion of total bile acids.

DISCUSSION

As shown in our previous report (4), certain indigestible polysaccharides seem to have an interfering action with the digestion and absorption of nutrients in the gut. In this study, the result of Na-alginate and konjac mannan feeding showed an increased secretion of pancreatic-biliary juice not only in the volume excreted but also for amylase activity and total bile acids. No significant effect was obtained from either agar or κ-carrageenan feeding.

Kanno (11) postulated that the stimulation of pancreatic exocrine secretion would occur in two phases: first, in the elimination phase and second, in the intake-synthesis phase. The former occurs in seconds or minutes, while the latter occurs after weeks, months or years. According to this concept, there seems to be present at least the two mechanisms by which pancreatic exocrine and biliary secretion can be increased. It is well known that the components of digested food such as essential amino acids or fatty acids as well as secreted gastric acid are the potent stimuli in releasing both cholecystokinin and secretin from the small intestine (12). However, this was not found to be the case in the present study, because, as shown in Fig. 2, single administration of each indigestible polysaccharide failed to increase the pancreatic-bile secretion. Schneeman (13) also reported that a continuous duodenal infusion of indigestible polysaccharides such as cellulose or pectin in conscious rats failed to stimulate pancreatic protein secretion. Therefore, the enhanced pancreatic-bile output observed after prolonged administration of indigestible polysaccharides would not be mediated through the release of cholecystokinin or secretin.

The second mechanism involves responding or adapting to long-term administration of the test diets. It is known that the pancreas may develop adaptive changes either morphologically or functionally. An increase in pancreas weight following administration of dietary fibers has been described before (4). As to the functional changes, it is also known that an administration of carbohydrate, fat or protein-rich diet generally leads to an elevation of amylase, lipase or protease activity in pancreatic juice, respectively (14–17). In this study, 5% carbohydrate was substituted with polysaccharides which was present in the diet at a low level. However, the results appeared sufficient to indicate an increase in pancreatic-bile secretion, when Na-alginate or konjac mannan was used for prolonged periods. It has been shown that a similar type of pancreatic juice secretion occurs when trypsin inhibitors are orally administrated to rats (18–21). In those experiments, trypsin
inhibitors induced not only pancreatic hypertrophy but also increased pancreatic enzyme secretion in rats. Trypsin inhibitors are known to bind trypsin, lower the enzymatic activity of trypsin and interfere with protein digestion in the small intestine.

Green and Lyman (20), Green et al. (22) and Miyasaka and Green (23) reported that the secretion of the pancreatic enzymes increased shortly after remove of pancreatic-bile juice from the intestine. They proposed that trypsin and/or chymotrypsin depress pancreatic enzyme secretion by means of negative feedback control.

Green and Nasset (24) observed that the presence of bile protected pancreatic enzyme activities in the intestine and regulated pancreatic biliary output. They (20, 24) suggested that protease and bile acids might have a role in the release of humoral factors existing in the mucosa of the intestinal wall.

As mentioned earlier (4), both Na-alginate and konjac mannans are more viscous than the other polysaccharides. The results of this experiment showed that these highly viscous polysaccharides might have slowed the rate of diffusion of the enzymes and nutrients in the gut, thereby lowering the rate of digestion and absorption.

Since Dooley and Valenzuela (25) reported that in human duodenum the receptors which are responsible for the volume and osmolarity changes in the intraluminal contents exist to regulate both pancreatic enzymes and bicarbonate secretion, the enhanced pancreatic function observed in this experiment seemed to be partially induced by the prolonged mechanical stimulation of the undigested foods.

As Na-alginate is more hydrophilic and viscous than konjac mannans, it is suggested that the gastric emptying of the polysaccharide-containing foods takes more time in the Na-alginate group of animals than in the konjac mannans group. Therefore, this delayed gastric emptying was thought to be responsible for the reduced food intake and the reduction of body weight gain in the Na-alginate group.
