Abstract

A large amount of wastewater is directly discharged into water bodies without treatment causing surface water contamination. Conventional treatment techniques produce lower effluent quality and are energy extensive. Rotating biological contactor (RBC) is an attractive biological wastewater treatment that offers a low energy footprint. However, its unstable removal efficiency makes it less popular. This study optimizes operating parameters in RBC combined with external membrane filtration (RBC-ME) in which the latter acts as a post-treatment step to stabilize the biological performance. Response Surface Methodology (RSM) was employed to optimize the biological and filtration performance by exploiting three parameters of disk rotational speed, hydraulic retention time (HRT), and sludge retention time (SRT). Results show that RBC-ME exhibits excellent biological treatment capacity and higher effluent quality. It attained 87.9 ± 3.2% of chemical oxygen demand, 45.2 ± 0.7% total nitrogen, 97.9 ± 0.1% turbidity, and 98.9 ± 1.1% ammonium removals. The RSM data demonstrated that the experimental data and model predictions agreed well. Under the most optimum parameters, the permeability of 144.6 L/m² h bar could be achieved at 36.1 rpm disk rotational speed, 18 h HRT, and 14.9 d SRT. This work demonstrates the effective use of statistical modeling to enhance RBC-ME system performance to obtain a sustainable and energy-efficient treatment process to prevent human health and the environment.

Article Highlights

- Membrane integrated RBC offers better biological performance than stand-alone RBC.
- Longer hydraulic and sludge retention time enhance permeability.
- Biofilm detachment limits the disk rotational speed.
- RSM helps to identify the significant operating factors and optimum levels with minimum effort and time.

1. Introduction

Biological methods have been widely adapted in wastewater treatment with the advantages of more cost-efficient, smaller footprint requirements, higher specific biomass activities, and sustainable and environmentally friendly (Liu et al., 2021; Fito et al., 2019). Stringent effluent standards imposed by regulatory authorities highlighting the need for the development of a sustainable and environmentally friendly treatment process (Ashraf et al., 2021; Preisner, 2020). Rotating biological contactors (RBC) rely on the rotating party submerged disks to grow biofilm that is kept in constant motion for energy-efficient aeration. The longer sludge retentions time (SRT) able the growth of the nitrifying community throughout the biofilm, to perform complete nitrication (Šíma et al., 2016). In RBC, sufficient microbial growth on the rotating disks exploits the benefit of high effluent quality and treatment efficiency. The RBC bioreactor has been utilized to achieve steady-state nitrification round the year and to improve removal efficiency and treatment capacity due to the liberty to multiplicate the mixed liquor suspended solids (MLSS). RBC operates at a high microbial concentration that allows a higher organic loading rate (Vasiliadou et al., 2016). Like in the membrane bioreactor, RBC can further be extended by incorporating membrane filtration for sludge separation. Recently, various RBC configurations appear as a promising alternative to the traditional treatment processes and they have been applied for the treatment of both municipal and industrial wastewaters (Waqas and Bilad, 2019).

Membrane integrated RBC has been explored to enhance the physical and biological operation of the bioreactor. Membrane integrated RBC employs membrane technology as post-treatment eliminating the need for a settling tank. The operational parameters, SRT, hydraulic retention time (HRT), and disk rotational speed have a considerable influence on microbial activity and membrane fouling potential (Su et al., 2019). These operational parameters can alter microorganism properties and helps in optimizing the system's performance. Recent studies have shown that short HRT results in a high organic loading rate which could increase the viscosity and sludge concentration as well as increase the filamentous bacteria growth (Deng et al., 2016). Recent studies have depicted that disk rotational speed, HRT, and SRT
influence the biodegradation process and micro-pollutant removal in membrane systems (Waqas et al., 2020a; Gkotsis et al., 2017).

The relationship and optimization of the operational parameters can help to increase the performance efficiency of the bioreactor. Hence, the design of experiments (DOE) is an excellent choice to optimize the process parameters. The DOE acquires fewer experiments and statistically predictable with highly reliable and efficient results. Response surface methodology (RSM) is an excellent example of such an approach in enhancing the performance efficiency of bioreactors and can study the behavior of various parameters simultaneously (Abdulgader et al., 2020). RSM is an empirical statistical technique that can investigate mathematical modeling to comprehend the mutual relationship of various process parameters on the response variable. The quantitative data is generated from the design of experiments and analysis of regression models and operational conditions can result in high-end performance (Belgada et al., 2020).

Biological wastewater treatment incorporating membrane separation has been the focus of research worldwide (Baneshi et al., 2020; Sheth et al., 2021; Bezirgiannidis et al., 2018). Some studies have focused on the optimization of the operating conditions of the membrane process. Askari et al., (Askari et al., 2018) studied RSM for the examination of the effect of process conditions on the NF membrane removal efficiency. The operational parameters, disk rotational speed, HRT, and SRT have a significant influence on microbial community concentration, biological performance, and membrane fouling propensity (Nuansawan et al., 2016; Deng et al., 2016). Disk rotational speed, HRT, and SRT can alter the extracellular polymeric substances secretion, sludge settling characteristics, and mixed liquor properties. However, no research work has been documented to optimize process parameters in RBC integrated with external membrane bioreactor using polysulfone membrane.

In this study, RSM modeling and optimization technique was utilized to investigate the relationship between different variables via establishing the predicted models. Box-Behnken design (BBD) through RSM was employed to examine the effect of three operational parameters (disk rotational speed, HRT, and SRT) on membrane permeability. The objective of this study is to investigate the relationship between operational parameters (disk rotational speed, HRT, and SRT) and the response parameter of permeability and to find the optimal condition of the process by using RSM. During experimentation, different operational parameters (disk rotational speed, HRT, and SRT) values were altered through variable speed shaft motor, an increase of organic loading rate and sludge wastage rate, respectively and performance of RBC combined with external membrane filtration (RBC-ME) bioreactor was analyzed. The optimization of membrane incorporated wastewater treatment process improves membrane permeability and reduces the operational cost of the process.

2. Methods And Materials

2.1. Wastewater preparation and bioreactor acclimatization

The lab-scale RBC-ME bioreactor was fed with the synthetic wastewater prepared by blending food leftover as suggested in our previous study (Waqas et al., 2020c) and achieved influent wastewater concentrations are summarized in Table 1.
Table 1

Influent characteristics for the RBC-ME bioreactor employing the polysulfone membrane in the post-treatment.

| Component     | Influent          |
|---------------|-------------------|
| COD (mg/L)    | 282.8 ± 8.3       |
| TN (mg/L)     | 2.5 ± 0.02        |
| Ammonia (mg/L)| 0.64 ± 0.07       |
| Nitrate (mg/L)| 0.54 ± 0.02       |
| Turbidity (NTU)| 14.6 ± 0.1       |
| pH            | 6.25 ± 0.03       |

RBC-ME: rotating biological contactor-membrane external, COD: chemical oxygen demand, TN: total nitrogen

2.2. Membrane preparation and properties

A flat sheet polysulfone (PSF) membrane was fabricated in-house and used during the experiments. The membrane was fabricated using PSF as polymer, polyethylene glycol (PEG) as an additive, and N,N-Dimethylacetamide (DMAc) as solvent through the phase inversion technique. PSF, PEG, and DMAc were used at a concentration of 12%, 1%, and 87% respectively. Detailed procedure for the manufacturing and characterization is given in our previous study (Waqas et al., 2021d). The dope solution was kept for 24h without any mixing to release the entrapped air bubbles. Entrapped air bubbles can cause defects in the membrane sheet hence air bubbles-free dope solution is necessary. The prepared dope solution was cast through the phase inversion method as described in our previous study (Waqas et al., 2021d).

2.3. Bioreactor set-up

The RBC-ME bioreactor consisted of a feed wastewater tank, RBC bioreactor and external membrane vessel was constructed in-house as shown in Fig. 1. The feed wastewater tank of capacity 42 L was used as a storage vessel to supply a constant supply of wastewater to the RBC bioreactor. The feed tank was facilitated with a mechanical stirrer to maintain the uniform concentration of wastewater throughout the storage vessel. The RBC bioreactor consisted of a 25×25×30 cm tank fabricated from poly (methyl methacrylate) and had a working volume of 6.5 L. The bioreactor was equipped with 5 rotating disks of 1.8 cm thickness and 18 cm diameter mounted on a stainless-steel shaft. The shaft was attached to a DC motor that rotates the disks. The disks were also fabricated from poly (methyl methacrylate) equivalent to a net surface area of 2034 cm² and placed inside the RBC bioreactor at 40% submergence. The disks were attached to polyurethane sheets (1.22–1.27 g/cm³ density) to colonize the microbial population. The flat sheet membrane module was placed after the RBC bioreactor acting as a post-treatment. The RBC-ME system did not include a settling tank (typically a part of a conventional RBC unit), which was replaced with a membrane filtration tank. The permeate was collected from the filtration cell and its volume was measured regularly.

2.4. Bioreactor operation

The lab-scale RBC-ME bioreactor was inoculated from the activated sludge obtained from the nearly full-scale domestic wastewater treatment plant. The bioreactor was operated for 45 days, divided into two phases. During the first phase, the bioreactor was operated on for 17 days to fully acclimatize the biofilm. The feed wastewater organic loading rate was kept constant at 19 g chemical oxygen demand (COD)/m² d and biofilm formed at the rotating disks was observed for any changes. The membrane panel was placed into the system after biofilm acclimatization and to study the impact of membrane permeability performance under various parameters.
The experimental investigation was done for three operating parameters (disk rotational speed, HRT, and SRT). The disk rotational speed was set from 30 to 50 rpm, HRT was set from 9 to 15 h and SRT was set from 5 to 15 days. The disk rotational speed was increased with the variable speed DC motor; flow rate was increased to increase the HRT while SRT was varied by wasting a portion of the reactor volume each day.

2.5. Analytical methods

COD, total nitrogen (TN), ammonia, and nitrate were measured using the specific Hach digestion solution (HACH, Loveland, USA) for each compound. The solution was diluted to fall into the range of the digestion vials being used for the study. The values were determined through Hach DR3900 Spectrophotometer (HACH, Loveland, USA). Hach 2100Q portable turbidimeter (HACH, Loveland, USA) and Hach HQ411D benchtop PH/MV meter (HACH, Loveland, USA) were used to determine turbidity and pH, respectively (APHA, 1997).

2.6. Determination of filtration performance

The low pressure for filtration not only reduces the energy cost, but it also is less susceptible to membrane fouling and maintains sustainable flux as reported elsewhere (Bilad et al., 2020). The membrane permeability \( (L) \), \( L/m^2 \) h bar) was calculated by using Eq. 1.

\[
L = \frac{\Delta V}{A \Delta t \Delta P}
\]  

(1)

where \( V \) is the volume of permeance (L), \( \Delta P \) transmembrane pressure (bar), \( t \) filtration time (h), and \( A \) membrane area \( (m^2) \).

2.7. Experimental design by RSM method

RSM is an aggregation of mathematical and statistical approaches accommodating to examine the effectiveness of various operational parameters. Design Expert software (DES) version 8.0.6 was applied to evaluate the response of various parameters (Zulfiqar et al., 2019; Malika and Sonawane, 2021). DES not only analyzes the parameters; it also helps to determine the projected outcomes to compare with the actual values. It can also help to predict the optimized values for the independent operational parameters (Zulfiqar et al., 2020a; Zulfiqar et al., 2020b). To scrutinize the impact of various operational parameters on the membrane fouling propensity in RBC-ME configuration, a 3-variables with 3-level BBD model was employed holding 3 central points per block. A 3-level BBD depicts that each numeric factor is varied over 3 levels. Three independent operational parameters are (i) disk rotational speed, (ii) HRT, and (iii) SRT. The BBD consists of three levels: high level or maximum (referred to as +1), medium level or central (referred as 0), and low level or minimum (referred as -1) for all operating parameters. The disk rotational speed varied from 30–50 rpm; HRT was in the range of 12–18 h while SRT was varied from 5–15 days. The independent variables and their range utilized are enrolled in Table 2. The 3 independent variables are presented as A, B and C respectively for statistical computations. The resulting response of membrane permeability was determined to investigate the influence of variables. The results of response date were analyzed with analysis of variance (ANOVA) if liable term composed a powerful effect (\( p \leq 0.05 \)). Evaluate model fit and transformation to graphs to interpret and evaluate the model prediction results.
Table 2
Independent variables and levels using in Box-Behnken design.

| Levels | Independent variable | Low level (-1) | Medium level (0) | High level (+1) |
|--------|----------------------|----------------|-----------------|-----------------|
| 1      | Disk rotational speed| 30             | 40              | 50              |
| 2      | HRT                  | 12             | 15              | 18              |
| 3      | SRT                  | 5              | 10              | 15              |

3. Results And Discussion

3.1. Biological performance

Table 1 summarizes the biological performance of the RBC-ME bioreactor employing the PSF membrane for synthetic wastewater treatment. The operation of RBC stabilized after approximately 30 d of operation ascribed from the profile of pollutant removals. The results enlisted in Table 1 were determined after the acclimatization time, showing a stable biological performance as depicted from steady removal efficiencies. The synthetic domestic wastewater used as the RBC feed contained a high number of organics. Therefore, carbonaceous bacteria undertaken the removal of the organics were expected to dominate in the biofilm. The high abundance of carbonaceous bacteria biodegraded the readily available substrate (organic pollutants). The RBC-ME bioreactor demonstrated excellent biological removal efficiencies in terms of COD, ammonium, TN, phosphorus, and turbidity (Table 1).

Table 3 summarizes the biological performance of the RBC-ME bioreactor employing the PSF membrane for synthetic wastewater treatment. The operation of RBC stabilized after approximately 30 d of operation ascribed from the profile of pollutant removals. The results enlisted in Table 3 were determined after the acclimatization time, showing a stable biological performance as depicted from steady removal efficiencies. The synthetic domestic wastewater used as the RBC feed contained a high number of organics. Therefore, carbonaceous bacteria undertaken the removal of the organics were expected to dominate in the biofilm. The high abundance of carbonaceous bacteria biodegraded the readily available substrate (organic pollutants). The RBC-ME bioreactor demonstrated excellent biological removal efficiencies in terms of COD, ammonia, TN, and turbidity (Table 3).
The results show significantly higher removal efficiencies for the COD, TN, ammonia, and turbidity of $87.6 \pm 2.7$, $45.2 \pm 2.6$, $98.5 \pm 0.07$, and $97.8 \pm 0.2$, respectively. The higher efficiency for COD and ammonia can be attributed to the high microbial activity of carbonaceous and ammonia oxidizing bacteria (Waqas et al., 2021c; b). An increase in effluent nitrate concentration ($1.8 \pm 0.2$) is due to poor anoxic conditions within the biofilm resulting in a low concentration of nitrate oxidizing bacteria. In the attached growth system, the relative position of the biofilm to the surface affects the oxygen concentration, being the lowest (anoxic) in the deeper part. It can be speculated that the formed biofilm on the substrate media was still too thin to exert the required anoxic condition for denitrification. Higher removal efficiency for turbidity was achieved by the RBC-ME bioreactor due to the membrane separation. The results showed the turbidity value substantially diminished from $14.6 \pm 0.1$ NTU to $0.32 \pm 0.03$ NTU in the RBC-ME attributes to $97.8 \pm 0.2\%$ removal efficiencies (Table 3).

Replacement of secondary settling tank with the membrane separation enabled the system to achieve removal efficiency not too dependent on the sludge settling characteristics (Waqas et al., 2020b). Any sludge produced by the detachment of the attached biofilm flocs on the substrate could readily be removed from the bioreactor. Removal of suspended biomass flocs resulted in higher nitrogen and phosphorous removal efficiencies as reported earlier (Mannina et al., 2018; Waqas et al., 2021a). The solid-liquid separation process ensures high effluent quality in terms of organics and nutrients. Consequently, the biological performance can be enhanced by increasing the biomass SRT.

### 3.2. Statistical analysis and model development

Table 4 shows three factors BBD matrix showing the independent variable and response of membrane permeability. The three operating parameters of disk rotational speed, HRT, and SRT were selected based on our earlier published data (Waqas et al., 2021c) according to their contribution to biodegradation and membrane fouling. The three-level BBD was used to perform the analysis with a total of 15 experimental runs. The permeability values over each set of parametric values were used to establish a statistical model.
Table 4
Box-Behnken design matrix for independent variable and response of membrane permeability at three-factor levels.

| Run | (A) Disk rotational speed (rpm) | (B) HRT (h) | (C) SRT (d) | Actual value | Predicted value |
|-----|-------------------------------|-------------|-------------|--------------|-----------------|
| 1   | 40                            | 15          | 10          | 138          | 137.33          |
| 2   | 30                            | 12          | 10          | 133          | 133.63          |
| 3   | 30                            | 15          | 15          | 139          | 139.38          |
| 4   | 50                            | 12          | 10          | 120          | 120.63          |
| 5   | 30                            | 15          | 5           | 133          | 132.63          |
| 6   | 40                            | 15          | 10          | 136          | 137.33          |
| 7   | 40                            | 12          | 5           | 131          | 130.75          |
| 8   | 50                            | 18          | 10          | 115          | 114.38          |
| 9   | 30                            | 18          | 10          | 140          | 139.38          |
| 10  | 50                            | 15          | 5           | 109          | 108.63          |
| 11  | 40                            | 18          | 15          | 142          | 142.25          |
| 12  | 40                            | 15          | 10          | 138          | 137.33          |
| 13  | 50                            | 15          | 15          | 125          | 125.28          |
| 14  | 40                            | 18          | 5           | 126          | 127.00          |
| 15  | 40                            | 12          | 15          | 140          | 139.00          |

3.3. RSM model optimization

Full fractional three-factor BBD was applied to investigate the effects of three independent parameters to model the steady-state membrane permeability. The results of the BBD model are described in common ANOVA (Table 5) in which the steady-state membrane permeability was set as the response (Zulfiqar et al., 2019). The ANOVA results show that the relationship between steady-state membrane permeability (units) and the experimental investigations fits well with a quadratic model with p values = 0.0069. The coded and actual factors for membrane permeability are shown in Eqs. (2) and (3).

\[
\text{Steady-state membrane permeability (L/m}^2\text{h bar) } = 137.33 - 9.50 A - 0.1250 B - 5.88 C - 3.00 AB + 2.50 AC + 1.75 BC - 9.29 A^2 - 1.04 B^2 - 1.54 C^2 \quad (2)
\]

\[
\text{Steady-state membrane permeability (L/m}^2\text{h bar) } = -39.16667 + 7.48333 \times \text{Disk rotational speed} + 6.26389 \times \text{HRT} - 1.34167 \times \text{SRT} - 0.1 \times \text{Disk rotational speed} \times \text{HRT} + 0.05 \times \text{Disk rotational speed} \times \text{SRT} + 0.11667 \times \text{HRT} \times \text{SRT} - 0.092917 \times \text{Disk rotational speed}^2 - 0.115741 \times \text{HRT}^2 - 0.061667 \times \text{SRT}^2 \quad (3)
\]

Eqs. 1 and 2 were used to predict the steady-state membrane permeability listed in Table 5, demonstrating a good agreement between the predicted and experimental data. The significance and authenticity of the proposed model were stated based on different model constraints for instance p values, R^2, adjusted R^2, as well as F values. A p-value < 0.0500
implies a model as significant and insignificant if p values are higher than 0.0500. $R^2$ represents the coefficient of determination used to validates the quality of the proposed model. A close to 1 value of $R^2$ is more advantageous. The proposed model depicts an $R^2$ value of 0.9951, which indicates that 99.51% variations of steady-state permeability are explicable across the parameter ranges. The adjusted $R^2$ value of 0.9862 is close to $R^2$ values, depicting the goodness of quadratic model fitting. The larger $R^2$ value confirms the excellent adaptation of the predicted model to the experimental data.

The quadratic model predicted an F-value of 111.89 which implicates that it is significant, with only a 0.01% probability it occurs due to noise. The model p-value less than 0.05 reveals the significant model terms. A p-value > 0.05 implicates the model term as non-significant. Table 5 shows that model terms A, C, AB, AC, BC and $A^2$ are significant while B, $B^2$, and $C^2$ are insignificant. A non-significant value for Lack of fit is required for a well-fit model. ANOVA shows a 1.06 lack of fit which implicates a non-significant relation to the pure error. It implies that the predicted quadratic model can be utilized to circumnavigate the design space.

A diagnostic plot such as the predicted versus actual values shown in Fig. 2 supports adjudicating the model satisfactoriness visually. Figure 2 indicates an adequate agreement between real data and the ones obtained from the models. A model normally can be considered reproducible if its coefficient of variance (CV) is less than 10%. The quadratic model represents a CV value of 0.8978% indicating good reproducibility of the model.

### Table 5

| Source            | Sum of Squares | df | Mean Square | F Value | p-value Prob > F |
|-------------------|----------------|----|-------------|---------|-----------------|
| Model             | 1393.08        | 9  | 154.79      | 111.89  | < 0.0001 Significant |
| A-Disk rotational speed | 722.00        | 1  | 722.00      | 521.93  | < 0.0001 Significant |
| B-HRT             | 0.1250         | 1  | 0.1250      | 0.0904  | 0.7758 Not significant |
| C-SRT             | 276.13         | 1  | 276.13      | 199.61  | < 0.0001 Significant |
| AB                | 36.00          | 1  | 36.00       | 26.02   | 0.0038 Significant |
| AC                | 25.00          | 1  | 25.00       | 18.07   | 0.0081 Significant |
| BC                | 12.25          | 1  | 12.25       | 8.86    | 0.0309 Significant |
| $A^2$             | 318.78         | 1  | 318.78      | 230.44  | < 0.0001 Significant |

#### 3.4. Process analysis

Membrane permeability is affected by operational parameters, that can exist in neutral, positive, or negative configurations. Those parameters can also significantly affect biological performance and effluent quality. Therefore, the study of the influence of these parameters on the steady-state membrane permeability can help to optimize the whole process (biodegradation and permeability). The dependency of the operational parameters on the membrane permeability is presented in Fig. 3 in the form of 2-D contour and 3-D response surface plots. Response surface diagrams illustrate regression equation models utilized to fathom the optimum status of multiple parameters, explains interactions between factors, and ultimately used to enhance the efficiency of the process.

Figure 3 shows the response surface plots for steady-state permeability. The plots are approximately symmetrical in shape with circular contours. Response surface plots indicate the relative importance of three operating parameters. All response plots demonstrate clear peaks, indicating the optimized parameter (disk rotational speed, HRT and SRT) values for the maximum value of the membrane permeability in the design space.

The 2-D contour and 3-D response surface plots in Fig. 3a and d reveal the interactions between the speed of the disk rotational and HRT pose a significant effect on the permeability. A lower disk rotational speed and higher HRT results in higher permeability. The decline in permeability can be described by the enhanced shear rate produced by higher disk rotational speed. The shear rate results in the shredding of biofilm flocs that suspend and block the membrane pores (Zhang et al., 2015; Luo et al., 2012). As the disk rotational speed increases to beyond 40 rpm, the permeability decreases. However, a less significant effect was found for the HRT because of the higher organics ratio and lower nitrogen concentration (Huang et al., 2011). All the organics are readily degraded and do not require higher HRT resulting in good performance even at low HRTs. Removal efficiencies decrease when moving away from these points, which means either a decrease or increase in any of the tested variables results in the decline of the permeability.

Figure 3b and e show the 2-D contour and 3-D response surface plots between disk rotational speed and SRT, depicting that higher disk rotational speed from 30 to 40 rpm at SRT values from 10 to 15 days leads to higher permeability; while beyond 40 rpm, the permeability gradually decreases. Shorter SRT results in poor settling of sludge increasing the membrane resistance by blocking the membrane pores (Jang et al., 2021). Higher SRT means retention of microbial community for a longer time in the bioreactor and thus lower sludge production.

The interaction between HRT and SRT as shown in Fig. 3c and f reveals that higher HRT and SRT increases, as also reported elsewhere (Berkessa et al., 2018). With the increase of both HRT and SRT from 12 h and 5 d, respectively, an increase in permeability is observed. Indeed, the membrane permeability further increases at higher HRT and SRT. HRT seems just slightly affect permeability. However, high SRT results in efficient settling of sludge and subsequently higher membrane permeability (Mannina et al., 2018). Overall, high values of both HRT and SRT favor higher permeability.

#### 3.5. Process optimization

The optimal condition of three process variables of disk rotational speed, HRT, and SRT for maximum steady-state permeability was examined based on the desirability function. Parameter optimization was performed to determine the
highest particular point, which amplifies the significant function i.e. steady-state permeability.

As shown in Fig. 4, the optimal conditions for maximum permeability (144.6 L/m² h bar) were found at a disk rotational speed of 36.1 rpm, HRT of 18 h, and SRT of 14.9 d, as shown in Fig. 4 and Table 7. The excellent agreement between predicted and experimental results confirms model validation to simulate the steady-state permeability.

| Variables       | Optimum values | Predictive | Experimental | Error (%) | Standard deviation |
|-----------------|----------------|------------|--------------|-----------|--------------------|
| Disk rotational speed | 36.1 rpm       | 144.6      | 144.5        | 0.44      | 1.18               |
| HRT             | 18.0 h         |            |              |           |                    |
| SRT             | 14.9 d         |            |              |           |                    |

To confirm the achieved results both from the experiments and model, two more experiments were performed using the optimum parametric values. Table 8 shows the experimental and model predictive values for the optimum condition. The steady-state permeability response of both the experimental and model values is in close agreement.

| Run | Predictive | Experimental | Error (%) | Standard deviation |
|-----|------------|--------------|-----------|--------------------|
| 1   | 143.5      | 143.00       | 0.35      | 0.26               |
| 2   | 137.3      | 137          | 0.18      | 0.13               |

4. Conclusions

This research applies RSM to optimize the biological and filtration performance of an RBC coupled with external membrane filtration. The RBC-ME bioreactor was a successful biological treatment process to achieve a high biological removal efficiency. The RBC exhibits 87.6 ± 2.7% of COD, 45.2 ± 2.6% TN, 98.5 ± 0.07% ammonia, and 97.8 ± 0.2% turbidity removal efficiencies. The RSM results demonstrated the effects of the operating parameters as well as their interactive effects on permeability as the response. At higher disk rotational speeds (> 35 rpm), the permeability decreased due to the higher shear rate and shredding of biofilm flocs. At higher HRT and SRT, higher permeability was obtained. By applying RSM, the optimum region for the bioreactor operating conditions was located. The optimum conditions obtained were 144.6 L/m² h bar permeability at disk rotational speed 36.1 rpm, 18 h HRT, and 14.9 d SRT. The results demonstrated good agreement amongst experimental and model predictions. It is evident from the current study that RSM is an efficient statistical optimization approach that can help to distinguish between the most important operational parameters at the
cost of minimum time and effort. The development of the membrane integrated RBC system can significantly enhance the effluent quality to satisfy the stringent regulations and can serve as a promising alternative for decentralized application for the development of a sustainable environment.

Declarations

Data Availability

The datasets generated during and/or analysed during the current study are available from the corresponding author on reasonable request.

Conflicts of Interests

The authors have no conflicts of interest to declare that are relevant to the content of this article.

Funding

This work was funded by the Yayasan Universiti Teknologi PETRONAS (YUTP) with grant code YUTP-015LC0-210.

Authors’ contribution

All authors contributed to the study conception and design. Material preparation, Conceptualization, Methodology, Investigation, Data curation, Formal analysis, Validation, Writing - original draft: Sharjeel Waqas; Funding acquisition, Supervision, Review & editing: Noorfidza Yub Harun; Conceptualization, Project administration, Resources, Supervision, Writing - review & editing: Muhammad Roil Bilad; Investigation, Data curation, Formal analysis: Taufik Samsuri; Supervision, Writing - review & editing: Nik Abdul Hadi Nordin.

Acknowledgements

The authors would like to thank the Universiti Teknologi PETRONAS for providing the research facilities.
