Abstract

We study the general relativistic (GR) effects induced by a spinning supermassive black hole on the orbital and spin evolution of a merging black hole binary (BHB) in a hierarchical triple system. A sufficiently inclined outer orbit can excite Lidov–Kozai eccentricity oscillations in the BHB and induce its merger. These GR effects generate extra precessions on the BHB orbits and spins, significantly increasing the inclination window for mergers and producing a wide range of spin orientations when the BHB enters LIGO band. This “GR-enhanced” channel may play an important role in BHB mergers.

1. Introduction

The detections of gravitational waves (GWs) from merging binary black holes (BHs; e.g., Abbott et al. 2018a, 2018b; Venumadhav et al. 2019; Zackay et al. 2019) have motivated many recent studies on the dynamical formation of such compact black hole binaries (BBBs). Dynamical formation channels include mergers arising from strong gravitational scattering in dense clusters (e.g., Portegies & McMillan 2000; O’Leary et al. 2006; Miller & Lauburg 2009; Banerjee et al. 2010; Downing et al. 2010; Ziosi et al. 2014; Samsing & Ramirez-Ruiz 2017; Gondán et al. 2018; Rodriguez et al. 2018; Samsing et al. 2018; Samsing & D’Orazio 2018) and more gentle “tertiary-induced mergers”—the latter can take place either in isolated triple/quadrupole systems (e.g., Antonini et al. 2017; Liu & Lai 2017, 2018; Silsbee & Tremaine 2017; Liu et al. 2019) or in nuclear clusters dominated by a central supermassive BH (SMBH; e.g., Antonini & Perets 2012; VanLandingham et al. 2016; Petrovich & Antonini 2017; Hamers et al. 2018; Hoang et al. 2018; Randall & Xianyu 2018; Frangione et al. 2019).

In this Letter we are interested in stellar-mass BHB mergers induced by an SMBH. Such BBBs may exist in abundance in the nuclear cluster around the SMBH due to various dynamical processes, such as scatterings and mass segregation (e.g., O’Leary et al. 2009; Leigh et al. 2018). Gravitational perturbation from the SMBH induces Lidov–Kozai (LK) eccentricity oscillations of the BHB, which leads to enhanced gravitational radiation and merger of the BHB. Our Letter examines several general relativistic (GR) effects that were overlooked in previous studies, but significantly impact the efficiency and outcomes of LK-induced mergers. We focus on isolated BHB–SMBH systems, and do not consider other processes related to scatterings and relaxation with surrounding stars in the cluster (e.g., VanLandingham et al. 2016; Petrovich & Antonini 2017; Hamers et al. 2018), which may also change the character of LK-induced mergers.

In the Standard LK-Induced Merger scenario, a BHB with masses $m_1$, $m_2$, semimajor axis $a_{in}$, and eccentricity $e_{in}$ moves around a tertiary ($m_3$) on a wider orbit with $a_{out}$ and $e_{out}$. The angular momenta of the inner and outer binaries are denoted by $L_{in}^{-}\equiv L_{in}/L_{in}$ and $L_{out}\equiv L_{out}/L_{out}$ (where $L_{in}$ and $L_{out}$ are unit vectors). If the mutual inclination between $\hat{L}_{in}$ and $\hat{L}_{out}$ (denoted as $I$) is sufficiently high, the inner binary would experience LK eccentricity oscillations on the timescale

$$t_{LK} = \frac{1}{\Omega_{LK}} = \frac{1}{n_{in} m_3} \left( \frac{a_{out,eff}}{a_{in}} \right)^3,$$

where $m_{12} \equiv m_1 + m_2$, $n_{in} = (Gm_{12}/a_{in}^3)^{1/2}$ is the mean motion of the inner binary, and $a_{out,eff} \equiv a_{out} \sqrt{1 - e_{out}^2}$ is the effective outer binary separation.

GR introduces pericenter precession of the inner binary, which can be described by the first-order post-Newtonian (PN) theory

$$\frac{d\omega_{GR}}{dt} = \frac{c^2 a_{in} m_{12}}{3 G m_{12} (1 - e_{in}^2)},$$

This precession competes with $\Omega_{LK}$, and tends to suppress LK oscillations or limit the maximum eccentricity $e_{max}$ (e.g., Fabrycky & Tremaine 2007; Liu et al. 2015). The general secular and quasi-secular equations of motion (see vector form in Liu et al. 2015; Liu & Lai 2018; Petrovich 2015), combined with the GW radiation, completely determine the evolution of the triple system. Such LK-induced mergers have been extensively studied (e.g., Blaes et al. 2002; Miller & Hamilton 2002; Wen 2003; Antonini & Perets 2012; Liu & Lai 2017, 2018; Silsbee & Tremaine 2017; Liu et al. 2019).

The spin vector ($S_i \equiv S_i \hat{S}_i$) of the BH is also coupled to the orbital angular momentum vector $L_{in}$ through de-Sitter precession (1.5 PN effect; e.g., Barker & O’Connell 1975):

$$\frac{d\hat{S}_i}{dt}_{\hat{S}_i \hat{L}_in} = \Omega_{S_i L_{in}} \hat{L}_{in} \times \hat{S}_i, \quad \Omega_{S_i L_{in}} = \frac{3 G m_{in} (m_2 + \mu_{in}/3)}{2 c^2 a_{in} (1 - e_{in}^2)},$$

where $\mu_{in} \equiv m_1 m_2/m_{12}$ is the reduced mass for the inner binary. A similar equation applies to the spinning body 2. To determine the final spin–orbit misalignments of the BHBs, it is essential to include this spin–orbit coupling effect in the scenario of the LK-induced merger. Our recent works (e.g., Liu...
& Lai 2017, 2018; Liu et al. 2019), focusing on the BHB mergers induced by stellar-mass tertiary (m₃ comparable to m₁, m₂), have shown that LK-induced mergers can give rise to unique signatures for the final spin–orbit misalignment angle θₘ₃ (see also Antonini et al. 2018; Rodriguez & Antonini 2018). In particular, for initially close BHBs (with a₀ ≲ 0.2 au), which can merge without the aid of the tertiary companion, modest (≪40°) θₘ₃ can be produced in the majority of triples (e.g., Liu & Lai 2017). For wide binaries (with a₀ ≳ 10 au), the distribution of θₘ₃ is peaked around 90° if the BHS have comparable masses (negligible octupole effect), while a more isotropic distribution of final spin axis is produced as the octupole effect increases (e.g., Liu & Lai 2018; Liu et al. 2019).

The Standard LK-Induced Merger mechanism, as outlined above (and studied in all previous works), includes the key GR effects associated with the inner binaries, but neglects the GR effects associated with the tertiary companion. This is adequate when the tertiary mass m₃ is not much larger than the masses of the inner BHB. However, for BHB–SMBH triples, with m₃ ≫ m₁, m₂, several GR effects involving the SMBH can qualitatively change the efficiency and outcomes of LK-induced mergers.

2. New GR Effects Involving SMBH Tertiary

We start by examining how various GR effects associated with the SMBH affect the LK oscillations and spin evolution of the inner BHB (see Figure 1).

(i) Effect I: Lense–Thirring Precession of Lout around S₃. For an SMBH, the spin angular momentum S₃ = λ₃Gm₃²/c (where λ₃ ≤ 1 is the Kerr parameter) can be easily larger than Lout = μ₄(1 − e₄²) (where μ₄ = (m₁m₂)m₄/m₄ and m₄ = m₁ + m₂). Thus Lout experiences Lense–Thirring precession around S₃ if the two vectors are misaligned (1.5 PN effect; e.g., Barker & O’Connell 1975; Fang & Huang 2019):

\[
\frac{dL_{\text{out}}}{dt} = \Omega_{\text{out}} S₃ \times L_{\text{out}},
\]

\[
\frac{de_{\text{out}}}{dt} = \Omega_{\text{out}} S₃ \times e_{\text{out}}
\]

\[
-3\Omega_{\text{out}} S₃ (\hat{L}_{\text{out}} \cdot \hat{S₃}) L_{\text{out}} \times e_{\text{out}},
\]

where the orbit-averaged precession rate is

\[
\Omega_{\text{out}} = \frac{GS₃(4 + 3m₂/m₃)}{2c^2a_{\text{out}}^3(1 − e_{\text{out}}^2)^{3/2}}.
\]

The back-reaction of Equation (4) implies that S₃ precesses around Lout at the rate Ω_{out}S₃/Lout/3.

As shown in Hamers & Lai (2017) in a different context, the variation of Lout can significantly affect LK eccentricity excitation when Ω_{out}S₃ becomes comparable to Ωₜₗₜ. As shown in Figure 1, Ω_{out}S₃/Lₜₗₜ ∼ 1 can be satisfied for sufficiently large m₃ (≥10⁶M☉). Moreover, LK oscillations can be affected or triggered due to an inclination resonance, which occurs when Ω_{out}S₃ matches Ωₜₗₜ, the precession rate of Lₜₗₜ around Lout (see below).

Figure 2 depicts an example of how various relativistic effects associated with the SMBH modify LK oscillations. The results are obtained by integrating the double-averaged (DA) secular equations of motion (averaging over both the inner and outer orbits; e.g., Liu et al. 2015; Liu & Lai 2018). We see that the BHB eccentricity exhibits regular oscillations in the "standard LK" case (black lines), but the inclusion of Effect I (Equations (4)–5) (purple lines) makes the eccentricity evolve chaotically and extend to higher values.

(ii) Effect II: de-Sitter-like Precession of Lin around Lout. The standard LK mechanism already includes the Newtonian precession of Lₜₗₜ around Lout (driven by the tidal potential of m₃ on the inner orbit), at the rate given by (to quadrupole order)

\[
\Omega_{\text{out}} = \frac{-3}{4} \Omegaₜₗₜ (\hat{L}_{\text{out}} \cdot \hat{L}_{\text{in}}) \quad \text{(for } e_{\text{in}} = 0) .
\]

The general equation for finite eₜₗₜ can be found in Liu et al. (2015). Note that for BHB–SMBH systems (m₃ ≫ m₁,m₂), dynamical stability requires a_{\text{out}} ≫ a_{\text{in}}. Thus, the octupole LK is negligible since e_{\text{out}} = [(m₁ − m₂)/(m₁ + m₂)]e_{\text{in}}a_{\text{out}}/(1 − e_{\text{in}}²) ≪ 1.
As explained in Hamers & Lai (2017), when $\gamma \sim 1$, an inclination resonance generates larger $I$ even from a small initial $I_0$, leading to a wider range of initial inclinations for extreme eccentricity excitation. Figure 3 explores these new GR effects by showing the $e_{\text{out}}$-excitation window as a function of $I_0$ for BHB–SMBH systems with given $m_1$, $m_2$, $a_{\text{in}}$, $a_{\text{out}}$ but different values of $m_3$ (thus different $\gamma$’s). The misalignment angle between $\hat{S}_3$ and $\hat{L}_{\text{out}}$ is set to 30°, but with a random azimuthal phase angle (i.e., the initial $\hat{L}_{\text{in}}$, $\hat{L}_{\text{out}}$, and $\hat{S}_3$ are not in the same plane). By evolving the triple system using the DA secular equations, we record $e_{\text{max}}$ achieved over an integration timespan of 500 $t_{\text{LK}}$ for each system with and without Effects I, II, and IV. In each panel, the cyan dots are the “standard LK” results; these can be calculated analytically (e.g., Liu et al. 2015). Note that since the octupole-order effects are negligible, systems with finite $e_{\text{out}}$ should exhibit a similar behavior as the cyan dots. We see that including Effects I–II (purple dots) can dramatically widen the eccentricity excitation window. As $\gamma$ approaches unity with increasing $m_3$, overlapping inclination and LK resonances give rise to the widespread chaos (e.g., Hamers & Lai 2017), causing systems with modest $I_0$ to attain extreme eccentricity growth.

When $e_{\text{max}}$ becomes sufficiently close to unity, the timescale of excursions to even more extreme values.

(iii) Effect III: de-Sitter Precession of $S_1$ around $L_{\text{out}}$. The “standard LK” already includes de-Sitter precession of $S_1$ around $L_{\text{in}}$. With an SMBH tertiary, $S_1$ also experiences a precessional torque from $m_3$:

$$\frac{d\hat{S}_1}{dt} \bigg|_{S_1L_{\text{out}}} = \Omega_{S_1L_{\text{out}}} \hat{L}_{\text{out}} \times \hat{S}_1,$$

with

$$\Omega_{S_1L_{\text{out}}} = \frac{3}{2} \frac{Gm_3 + \mu_{\text{out}}/3}{c^2a_{\text{out}}(1 - e_{\text{out}}^2)}.$$

Note that $\Omega_{S_1L_{\text{out}}} = \Omega_{L_{\text{in}}L_{\text{out}}} (\text{Equation (9)}).$ The back-reaction torques on $L_{\text{out}}$ and $e_{\text{out}}$ can be safely neglected since $L_{\text{out}} \gg S_1$. Although Equation (11) does not affect the orbital evolution of the inner binary, it does affect the evolution of $S_1$ and the spin–orbit misalignment angle $\theta_{\text{sl}}$

The bottom panel of Figure 2 shows several examples of the evolution of $\theta_{\text{sl}}$ during LK oscillations, with and without various GR effects. The evolution of $S_1$ is governed by two

---

**Figure 2.** Sample orbital and spin evolution of a BHB with an SMBH tertiary. The three panels show the eccentricity, the inclination of the inner BH binary (the angle between $\hat{L}_{\text{in}}$ and $\hat{L}_{\text{out}}$), and the spin-orbit misalignment (the angle between $\hat{S}_1$ and $\hat{L}_{\text{out}}$). The parameters are $m_1 = 30 M_\odot$, $m_2 = 20 M_\odot$, $a_{\text{in}} = 0.1$ au, $m_3 = 2.3 \times 10^5 M_\odot$, $a_{\text{out}} = 500$ au, $e_{\text{out}} = 0$, and the initial $e_{\text{in}} = 0.001$, $I_0 = 84^\circ$ and $\theta_{\text{sl}}^0 = 0^\circ$. The color-coded trajectories represent the evolution with various effects included (as labeled). Gravitational radiation is not included in these examples.
is only a few times larger than similar. The BH spin evolution, and thus does not play a role in the plot. We have also done calculations that do not include Effect IV, and found that the result is integrating SA secular equations 30

"adiabaticity parameters":

\[ A = \left| \frac{\Omega_{S1,\text{in}}}{\Omega_{L,\text{out}}} \right|, \quad B = \frac{\Omega_{S1,\text{in}}}{\Omega_{S1,\text{out}}}. \]  

(13)

We expect (i) when \( A, B \ll 1 \) (“nonadiabatic”), the spin axis \( \hat{S}_i \) cannot “keep up” with the rapidly changing \( \hat{I}_{\text{in}} \), and thus effectively precesses around \( \hat{L}_{\text{out}} \), keeping \( \theta_{S1,\text{pre}} \approx \) constant (note that since \( \Omega_{S1,\text{out}} = \Omega_{L,\text{in}} \) is only a few times larger than \( \Omega_{L,\text{in}} \), see Figure 1—\( \theta_{S1,\text{out}} \) is only approximately constant as \( \hat{L}_{\text{out}} \) precesses around \( \hat{S}_3 \)); (ii) when \( A, B \gg 1 \) (“adiabatic”), \( \hat{S}_1 \) closely “follows” \( \hat{I}_{\text{in}} \), maintaining an approximately constant \( \theta_{S1} \). (iii) In the regime between (i) and (ii) (“trans-adiabatic”), the evolution of \( \hat{S}_1 \) can be quite complicated and chaotic, because of its dependence on \( e_{\text{in}} \) during the LK cycles (see Storch et al. 2014; Storch & Lai 2015; Anderson et al. 2016, 2017; Liu & Lai 2017, 2018).

As the BHB orbit decays, the system may transition from “nonadiabatic” at large \( a_{\text{in}} \) to “adiabatic” at small \( a_{\text{in}} \), where the final spin–orbit misalignment angle \( \theta_{S1}^f \) is “frozen.” From Figure 1, we see that, because of the contribution of \( \Omega_{L,\text{in}}^{\text{GR}} \) to \( \Omega_{L,\text{out}} \), the conditions \( A, B \ll 1 \) can be easily satisfied initially for systems with \( m_3 \gtrsim 10^6 M_\odot \). As these systems experience LK-induced orbital decay, they must go through the “trans-adiabatic” regime and therefore may attain a wide range of \( \theta_{S1}^f \) (see below).

(iv) Effects IV. Both \( \hat{I}_{\text{in}} \) and \( \hat{S}_1 \) (and \( \hat{S}_2 \)) experience Lens–Thirring precession around \( \hat{S}_1 \) at the rate

\[ \Omega_{L,\text{in}} = \Omega_{S1,\text{out}} = \Omega_{L,\text{in}} = - \frac{GS_3}{2c^2 a_{\text{out}}^3 (1 - e_{\text{out}}^2)^{3/2}}. \]  

(14)

Since \( \Omega_{L,\text{in}}/\Omega_{S1,\text{out}}^{\text{GR}} = \Omega_{S1,\text{out}}/\Omega_{S1,\text{in}} \approx v_{\text{out}}/c \) (where \( v_{\text{out}} \) is the orbital velocity of the outer binary), they can be neglected when \( v_{\text{out}} / c \ll 1 \).

3. Binary BH Mergers Induced by SMBH

We now add gravitational radiation to our fiducial example (Figure 3 with \( m_3 = 2.3 \times 10^6 M_\odot \)). Since Effect IV is not important in this example, we perform two sets of calculations with and without Effects I-III, and evolve the system until the BHB enters the LIGO band (i.e., when the peak GW frequency reaches 10 Hz). The results are summarized in Figure 4.

In the “standard LK” mechanism (without Effects I-III; cyan circles in the top two panels of Figure 4), for systems with negligible octupole effects, the merger time can be well approximated by (e.g., Liu & Lai 2018)

\[ T_m \approx T_{m,0}(1 - e_{\max}^2)^{3/2}, \]  

(15)

where \( T_{m,0} = (5 c^2 a_{\text{in}}^4 / (256 G^2 M_\odot^2 \mu_{\text{in}})) \) is the merger time due to GW emission for an isolated circular BHB (e.g., Peters 1964; \( T_{m,0} \approx 10^9 \) yr for the systems considered in Figure 4), and \( e_{\max} \) is the maximum eccentricity achieved in the LK cycle (see Figure 3). When the GR effects associated with the SMBH are

![Figure 3](image-url)
are the same as those in Figure 3 with mergers in the presence of a tertiary Liu & Lai 2017; see the dashed line. However, when the GR effects associated with the SMBH are included, the final BH spin orientation is significantly “randomized.” Given the wide distribution of $\theta_{\text{fin}}^{\text{c}}$, we find the large spread in $\chi_{\text{eff}}$ in the bottom panel of Figure 4, where $\chi_{\text{eff}} = (m_1 \chi_1 + m_2 \chi_2) \cdot \hat{L}/m_2$ (with $\chi_2 = \mathfrak{S}_{\text{c}}^2/(Gm_2^3)$) is the effective binary spin parameter that can be directly measured from GW observations. Note that the two spins in the merging binary BHs are strongly correlated (see also Liu et al. 2019; Figure 10); this is different for the scenarios involving strong scattering, which expectedly produce uncorrelated isotropic spins.

Due to the negligible octupole effect in BHB–SMBH systems, the “residual” eccentricities of merging BHs (when they enter the 10 Hz LIGO band) are all below 0.1 in our simulations. This is in contrast to binary mergers induced by the stellar-mass tertiary studied in Liu et al. (2019).

4. Summary and Discussion

We have identified the impacts of several GR effects in BHB–SMBH triples that have been little explored. Effect I (Equations (4)–(6)) allows the BHB eccentricity to reach extremely high values even with modestly inclined or nearly coplanar outer orbits. Effect II (Equations (8) and (9)) modifies the eccentricity growth (when combined with Effect I) and BH spin evolution indirectly. Effect III (Equations (11) and (12)) only affects the spin evolution. The overall dynamics of the BHB and BH spin around an SMBH can be characterized by the dimensionless rates (Equations (10) and (13)). Effects I and II generally require very massive SMBH $(m_3 \gtrsim 10^8$–$10^9 M_\odot)$ to be effective, while Effect III can be important for a wide range of SMBH masses (see Figure 1). Overall, these GR effects can significantly widen the LK-induced merger window and increase the merger fraction. They also produce a broad distribution of the final BH spin–orbit misalignment angles, leading to a wide range of the effective BHB spin parameter $\chi_{\text{eff}}$.

Our proof-of-concept calculations have demonstrated the importance of the GR effects in BHB–SMBH systems. However, we have not thoroughly explored the relevant parameter space, nor considered various “environmental” effects associated with BHs in nuclear cluster. We leave these to future works.

We thank Jean Teysandier and Clifford Will for useful discussion and communication. This work is supported in part by the NSF grant AST-1715246 and NASA grant NNX14AP31G.
