Excitotoxicity is considered to be an important mechanism involved in various neurodegenerative diseases in the central nervous system (CNS) such as Alzheimer’s disease (AD). However, the mechanism by which excitotoxicity is implicated in neurodegenerative disorders remains unclear. Kainic acid (KA) is an epileptogenic and neuroexcitotoxic agent by acting on specific kainate receptors (KARs) in the CNS. KA has been extensively used as a specific agonist for ionotrophic glutamate receptors (iGluRs), for example, KARs, to mimic glutamate excitotoxicity in neurodegenerative models as well as to distinguish other iGluRs such as α-amino-3-hydroxy-5-methylisoxazole-4-propionate receptors and N-methyl-D-aspartate receptors. Given the current knowledge of excitotoxicity in neurodegeneration, interventions targeted at modulating excitotoxicity are promising in terms of dealing with neurodegenerative disorders. This paper summarizes the up-to-date knowledge of neurodegenerative studies based on KA-induced animal model, with emphasis on its potentials and limitations.

1. Introduction

Excitotoxicity is involved in a variety of neurodegenerative disorders in the central nervous system (CNS) including Alzheimer’s disease (AD), Parkinson disease (PD), amyotrophic lateral sclerosis (ALS), and multiple sclerosis (MS). In the past decades, great achievements have been obtained in elucidating excitatory signaling pathways, yet the mechanism by which glutamate receptors is implicated in neurodegenerative disorders remains unclear. Kainic acid (KA), an analog of excitotoxic glutamate, can elicit selective neuronal death in the brain of rodents, of which the pathological changes partially mimic neurodegeneration in the CNS. Thus, KA-induced neurodegeneration in rodents has been used as a model for exploring the pathogenesis of excitotoxicity in neurodegenerative disorders.

2. Generic Characteristics of KA and KA Receptors (KARs)

KA was originally isolated from the seaweed called “Kaininsou” or “Makuri”. The molecular formula of KA are \( \text{C}_{10}\text{H}_{12}\text{NO}_4 \) and the molar mass of KA is 213.23 (Figure 1). Initially, KA was used as an antihelminth compound to remove worms from the gut. Subsequent studies indicated that KA is a nondegradable analog of glutamate and a potent neurotoxin [1]. KA exerts its neuroexcitotoxic and epileptogenic properties by acting on kainate receptors (KARs). Upon binding to KARs, KA induces a number of cellular events, including the influx of cellular \( \text{Ca}^{2+} \), production of reactive oxygen species (ROS), and mitochondrial dysfunction leading to neuronal apoptosis and necrosis [2]. KA has been extensively utilized as a specific agonist for ionotrophic glutamate receptors (iGluRs); that is, KARs to mimic the
3. Features of KA-Induced Neurodegenerative Animal Model

Systemic (intravenous or intraperitoneal), intranasal, or local administration of KA results in a series of clinical manifestations and pathological changes in rodents, including recurrent seizures, behavioral changes of rodents, oxidative stress including the generation of ROS and reactive nitrogen species (RNS), hippocampal neuronal death and glial activation, and so forth [2].

3.1. KA Induces Recurrent Seizures and Behavioral Changes in Rodents. In rodents, systemic administration of KA leads to a well-characterized seizure syndrome [5, 6]. During the first 20–30 minutes, the animals show “staring” spells, followed by head nodding. Then, they stand upright and fall down, with wet-dog shakes for around 30 minutes. One hour after KA administration, the animals start to present with recurrent limbic motor seizures. The limbic seizures then develop into status epilepticus and lasted 1-2 hours [7]. After KA administration, rodents show behavioral changes in the water maze, the object exploration tasks, and the open-field test in association with selective damage in the hippocampus. Deficiency in short-term spatial memory and long-term spatial learning, a higher degree of anxiety [8], and depression-like behaviors were also observed [9]. Physical exercise and selective cyclooxygenase (COX)-2 inhibitors like celecoxib may help to enhance the function recovery [10, 11].

3.2. Selective Hippocampal Neurodegeneration in Rodents after KA Challenge. Among the agents used to selectively destroy hippocampal neurons, ibotenic acid (IBO) and N-methyl-D-aspartate (NMDA) are nonspecific in acting on different cell types and usually these toxins do not cause seizures. In contrast, focal injection of KA resulted in hippocampal damage that occurred primarily in the CA3 area [12]. Similar selective vulnerability to KA was also seen when KA is administered via systemic injection. Selective vulnerability of hippocampal neurons was related to the distribution of the AMPARs/KARs in the brain [13]. KARs are most abundant in CA3 region and the activation of KARs can induce the production of ROS and compromise the function of mitochondria in the region [14, 15]. The stimulation of KARs excites CA3 neurons directly and increases glutamate efflux [16, 17]. Systemic injection of KA produced extensive neuronal death, primarily within the hippocampus hilus, CA3, and CA1 areas [18]. The hilar neurons are sensitive to KA-induced excitotoxicity, but neuronal loss in the other hippocampal areas varies between animal species and strains [19, 20]. KA at higher doses can also induce neurotoxicity in the medial amygdaloid nuclei [21].

KA-caused neuronal death involves endoplasmic reticulum (ER) stress, activation of ER sensor proteins, and induction of the fragmentation of the ER membrane [22], as well as Ca2+ overload [2]. C-jun N-terminal kinase (JNK)3 plays a detrimental role whereas other MAPKs like p38 and extracellular signal-regulated kinases 1/2 (ERK 1/2) seem to play a beneficial role [23]. Ikappa B kinase (IkB)/nuclear factor-kappa B- (NFkB-) dependent microglia activation contributes to KA-induced hippocampal neuronal death in vivo through induction of inflammatory mediators like tumor necrosis factor (TNF)-α and interleukin (IL)-1β [24].

3.3. Glial Activation after KA Treatment. KA binds to KARs expressed on neurons and microglia, leading to (1) rapid Ca2+ influx, (2) activation of Ca2+-dependent enzymes and generation of ROS and RNS, (3) excessive Ca2+, ROS and RNS lead to mitochondrial dysfunction, and (4) nuclear condensation and DNA fragmentation. Alternatively, intense Ca2+ overload can directly cause mitochondrial swelling and damage, causing acute neuronal cell death [2]. KA-induced neuronal death is accompanied by the activation of gliocytes, that is, microglia and astrocytes, characterized by the clustering of activated gliocytes in the hippocampal lesions [25, 26]. Microglia are the main effector cells of the inflammatory responses in the CNS, exert their functions as phagocytes, and interact with other gliocytes and neurons [27]. The physiological role of microglia can be partly linked to neuroprotection whereas under pathophysiological conditions, microglia may become activated and secrete a great amount of proinflammatory cytokines, chemokines, complements,
Figure 2: KA-induced microglial activation. Activated microglia express MHC class I and II, costimulatory molecules (CD80 and CD86), chemokine receptors (CCR2, 3, 5, CXCR3, 4, etc.), cytokine receptors (IL-10R, IL-12R, IL-18R, IFNgR, TNFR, TGFβR, etc.), complement receptors (FCyRIII and CR1, 3, 4, etc.), and prostaglandin receptors, produce complements, prostaglandins, cytokines (IL-1, IL-6, IL-10, IL-12, IL-18, TNF-α, TGF-β, etc.), chemokines (IP-10, MIP-1α, MIP-1β, MCP-1, IL-8, RANTES, etc.), ROS, and RNS, and secrete neutrophins (NGF, BDNF, and NT-3, 4, etc.), proteases, and excitatory amino acids, which may either contribute to excitotoxic damage or be protective against KA damage. IL: interleukin; CCR: C-C chemokine receptor; CXCR: CXC chemokine receptor; IFNgR: interferon gamma receptor; TNF: tumor necrosis factor; TGF: transforming growth factor; IP: Interferon gamma-inducible protein; MIP: macrophage inflammatory protein; MCP: monocyte chemotactic protein; RANTES: regulated upon activation, normal T-cell expressed and presumably secreted; NGF: nerve growth factor; BDNF: brain-derived neurotrophic factor; NT: neurotrophin.

and so forth [28]. Activated microglia may play a neuroprotective role in MS and its animal model, experimental autoimmune encephalomyelitis (EAE), by facilitating reparatory and regenerative processes [29]. However, in other neurodegenerative diseases such as AD and PD, microglia may initiate and aggravate the disease process through secreting proinflammatory and cytotoxic factors [30, 31]. In KA-induced excitotoxic neurodegeneration, activated microglia express MHC class I, MHC class II, and costimulatory molecules, produce complements, cytokines (IL-1, IL-6, IL-12, IL-18, TNF-α, etc.), chemokines, ROS, and RNS, and secrete proteases and excitatory amino acids, which contribute to the neuronal death [27, 28, 32] (Figure 2). Stanniocalcin 2 (STC2), the paralog of STC1, exerts neuroprotective actions against excitotoxic insults of KA through direct inhibition of microglial activation [33]. Despite the important role of microglia in KA-induced neurodegeneration, evidence is lacking that microglia participates in initiating the inflammatory and degenerative process. Seemingly, activation of microglia is just a “byproduct” of KA-induced excitotoxicity, but serves as an “accomplice” in this process [34].

Astrocytes were formerly regarded as passive supporters of neurons for decades. However, a new concept of neuronal-glial intercommunication that astrocytes play a dynamic role by integrating neuronal inputs and modulating synaptic activity, whereby contributing to neurodegenerative development, has been recently acknowledged [35, 36]. Astrocytes can prevent neurons from death and promote proliferation and differentiation of precursor cells by producing growth factors [37–39]. Moreover, astrocytes express functional receptors for the excitatory neurotransmitters like iGluRs [40]. In pathological conditions, astrocytes may contribute to brain damage by releasing ROS and proinflammatory factors. Failure in water transport also triggers brain edema, reversal of neurotransmitter transporters, and Ca2+-dependent exocytosis. Furthermore, the opening of high-permeability plasmalemmal channels contributes to glutamate excitotoxicity [41]. The expression of glial fibrillary acidic protein (GFAP), a marker for astrogliosis, was shown to steadily increase as early as one day after intrahippocampal or intraperitoneal injection of KA [42, 43]. Aged astrocyte specifically induced substance (OASIS) is known to be expressed on astrocytes and involved in the ER stress [44], which plays an important role in attenuating neuronal damage induced by KA [45]. Upregulated transcription factors in astrocytes, including NF-κB and nuclear factor erythroid-2-related factor 2 (Nrf2) induce the expression of neuroprotective molecules [46, 47].
3.4. KA-Mediated Oxidative Stress. KA receptors have both presynaptic modulatory and postsynaptic excitatory actions [48, 49]. The activation of KA receptors leads to membrane depolarization and increased influx of cellular calcium, which are required to trigger the cascade of neuronal death [50]. ROS/RNS have been implicated in the pathogenesis of various neurodegenerative disorders [51]. KA administration increases the generation of ROS and RNS. The increased formation of thiobarbituric acid-reactive substances (TBARS) and decreased total antioxidant status (TAS) in the cerebral cortex, cerebellum, and brain stem of rats subjected to KA indicate the presence of oxidative stress in excitotoxicity [52]. The exact mechanisms regarding the increased production of nitric oxide (NO) in excitotoxicity are not well established. However, stimulation of KARs induces NO release, which, in turn, modulates glutamate transmission [53]. NO may induce changes in neuronal signaling pathways [54]. Generation of other free radicals also contributes to neuronal damage [55]. KA induces immediate production of COX-2 that is involved in hippocampal neuronal death [56]. COX-2 facilitates the recurrence of hippocampal seizures and stimulates hippocampal neuronal loss after KA administration [57, 58]. PGE(2), the synthesis of which is dependent on COX, is pathologically increased in the brain after KA treatment, in close association with neuronal death [59]. In addition, seizure-induced products of lipid peroxidation, such as F(2)-isoprostanes and isofurans, play critical roles in the initiation and modulation of inflammation and oxidative stress, serving as reliable indices of oxidative stress in vivo [60].

3.5. KA-Enhanced Inflammatory Mediator Production. Neurodegeneration is associated with increased inflammatory mediators in the CNS such as in AD, MS, and so forth [61, 62]. Activated microglia and astrocytes after KA treatment release a large amount of inflammatory mediators such as NO, IL-6, IL-12, TGF-β, TNF-α, IL-18, and IL-1β [28, 63, 64]. Manipulation of inflammatory mediators may affect the outcome with regard to seizure activity, behavioral changes, as well as the neuropathological consequences in KA-induced neurodegeneration [65]. Important inflammatory mediators including NO, IL-6, TGF-β, TNF-α, IL-12, IL-18, and IL-1β are herein summarized.

The production of NO represents one of the principle features of activated macrophage/microglia, and NO is a major effector in the innate immunity [66]. NO can be formed enzymatically from L-arginine by inducible NO synthase (iNOS) in neuroglia [67]. KA administration increases the generation of ROS and RNS by neuroglia. Microglia can produce large amounts of soluble factors like NO [68]. Elevated production of NO by increased activity of iNOS is thought to contribute to KA-induced neuronal damage [69]. iNOS-deficient mice are resistant to KA-induced neuronal death [70]. Similarly, pretreatment with aminoguanidine, a selective iNOS inhibitor, significantly suppressed KA-induced neuronal death in the hippocampal CA3 area with concomitant decrease in iNOS expression and microglial activation [70].

IL-6, which is secreted by macrophages, dendritic cells, T cells, and so forth, bears both pro- and anti-inflammatory functions. IL-6 was initially categorized into a T helper (Th) 1 cytokine [71]. However, IL-6 can induce IL-4 production by naive Th0 cells and their differentiation into effector Th2 cells [72]. IL-6 appears to be a critical factor in early phases of CNS insults, taking part in the orchestration of attempts for tissue repair [69]. Levels of IL-6 are increased in the cerebrospinal fluid (CSF) in humans after tonic-clonic seizures [73]. IL-6 mRNA is increased in the hippocampus, cortex, amygdale, and meninges, and IL-6 receptor is upregulated in the hippocampus in the rat brain after KA-induced status epilepticus [73]. Neuronal death is more pronounced when IL-6 is produced in limbic seizures induced by KA [26]. Upregulated expression of IL-6 represented an endogenous neuroprotective mechanism against NMDAR-mediated injury in cerebral ischemia [74]. IL-6 knockout mice exhibit significantly higher seizure susceptibility to NMDA, AMPA, and KA, and the excitatory amino acid system seems more active in the CNS of IL-6 deficient mice [75]. Specifically, IL-6 deficiency increases neuronal injury and impaired the inflammatory response after KA treatment, characterized by reduced reactive astrogliosis and microgliosis versus increased morphological hippocampal damage, oxidative stress, iNOS expression, and apoptotic neuronal death [76].

IL-12 consists of p35 and p40 subunits, which form the bioactive IL-12p70 when combined together. IL-12 is required for the induction of IFN-γ production, critical for the polarization of the Th1 immune response. In EAE, the proinflammatory cytokines IL-12, IFN-γ, TNF-α, IL-1β, IL-6, and IL-18 are involved in the initiation and development of the local immune responses in the CNS [77]. IL-12 can be produced by activated microglia in response to KA, and IL-12p35 deficiency may alleviate hippocampal injury upon KA challenge, indicating a critical role of IL-12 in excitotoxic-induced brain injury [65]. Moreover, expression IL-12 was increased in IL-18 deficient mice as compared with controls in association with increased microglial activation, suggesting that the null role of IL-18 in excitotoxic injury may be compensated by the upregulated levels of IL-12 [78].

TGF-β bears anti-inflammatory, immunosuppressive, and neuroprotective features. It can downregulate (micro)glial cytokine production, for example, IL-1 and TNF-α [69]. TGF-β1 mRNA in the regenerating neurons is correlated with glial activation [79]. Exogenous administration of TGF-β1 protects excitotoxic lesions and neuronal death [80]. TGF-β1 mRNA is also increased in the hippocampus after KA-induced seizures, particularly in the areas of neurodegeneration [81]. TGF-β3 is upregulated in response to KA, and exogenous TGF-β3 significantly attenuates KA-induced seizures and neuronal loss in a dose-dependent manner, indicating a protective role of TGF-β3 [82].

TNF-α is mainly produced by microglia and astrocytes in the CNS. KA-activated microglia expressed high levels of TNF-α mRNA and protein. As with many other cytokines, TNF-α bears neuroprotective properties in contrast to its well-known deleterious role as a proinflammatory cytokine,
which implies an intricate biological balance in immune and inflammatory responses mediated by TNF-α [83]. The mechanisms by which TNF reduces brain injury may involve the upregulation of proteins, such as neuronal apoptosis inhibitor protein (NAIP), which maintains calcium homeostasis or reduces free radical generation [84]. The protective roles of TNF-α in KA-induced neurodegeneration can also be mediated via TNFR2 signaling pathway [85]. However, inconsistent findings suggested that TNF-α derived from KA-activated microglia can increase the excitotoxicity of hippocampal neurons and can induce neuronal apoptosis in vitro and in vivo [86].

IL-1β is a proinflammatory cytokine which can enhance postsynaptic AMPAR responses in CA1 pyramidal neurons via the release of glutamate, thereby facilitating basal hippocampal synaptic transmissions [87]. IL-18 knockout mice showed a diminished microglial activation and reduced dopaminergic neuronal loss after acute 1-methy-4-phenyl-1,2,3,6-tetrahydropyridine (MPTP) treatment [88]. In KA-induced excitotoxicity, IL-18 immunoreactivity was found in the hippocampal microglia of mice whereas IL-18R immunoreactivity was observed in astrocytes. Levels of IL-18 and IL-18R in the hippocampus were upregulated progressively from day 1 and reached the peak on day 3 post-KA treatment [89]. We found that exogenous administration of IL-18 aggravated KA-induced injuries in C57BL/6 mice, and IL-12 could compensate the function of IL-18 and worsen seizure severity as well as hippocampal neurodegeneration in IL-18 deficient mice [78].

IL-1β, a proinflammatory cytokine produced in abundance by activated microglia, acts as a regulatory factor in the multiple connections among the immune, nervous, and endocrine systems. IL-1β exerts its effects through IL-1 receptor type 1 (IL-1R1) and IL-1 receptor accessory protein (IL-1RACP) [90]. IL-1β plays a pivotal role in the neuroinflammation associated with certain forms of neurodegeneration, including cerebral ischemia and excitotoxic brain injury [91]. Compelling evidence in experimental neurodegenerative models indicates that IL-1β is pivotal in the excitotoxicity leading to neuronal death [92]. Primary cultured microglia are significantly activated by KA with increased IL-1β levels [93]. IL-1β can mediate KA-induced excitotoxic injuries to hippocampal neurons in vitro and in vivo [93].

4. Neurodegenerative Animal Model Induced by Intranasal Administration of KA: Our Experience

C57BL/6 mice are commonly used for transgenic studies, while they are resistant to systemic administration of KA (intravenous or intraperitoneal). However, Chen et al. in our group, developed a model of KA-induced neurodegeneration by intranasal administration of KA into C57BL/6 mice [94]. This model provides a valuable tool to explore the role of excitotoxicity in neurodegeneration using transgenic mice with C57BL/6 background. Within 15 minutes after KA administration, C57BL/6 mice are catatonic and staring, followed by myoclonic twitching, frequent rearing, and repeated falling. Approximately 30–40 minutes after administration, the mice present with status epilepticus, which lasts 1–5 hours. Some serious cases die from seizures. Then the mice assume a hunched posture and remain immobile for additional few hours [78]. As to behavioral changes, intranasal administration of KA induced elevated levels of spontaneous activity in the open-field test [94].

The mechanism as regards how KA induces excitotoxic neurodegeneration through intranasal administration is underclarified whereas we have several speculations. Firstly, KA may reach the hippocampus via passive diffusion, a route utilized extensively in both clinical practice and laboratory investigations [95]. Secondly, KARs were found in olfactory nerves and the olfactory bulb [96]. Protracted postsynaptic stimulation induced by KA can be relayed through projections to the hippocampus and thus result in neuronal damage. Thirdly, KA may directly enter the CSF via the nasal cavity, since the CSF has direct connection with the nasal cavity to the CSF [98]. Finally, KA may reach the hippocampus via the blood circulation [99].

5. Potentials of Antiglutamate Excitotoxicity as a Therapeutic Target

Considering the importance of oxidative stress in KA-induced excitotoxic damage, antioxidant and anti-inflammatory treatments may attenuate or prevent the neurodegenerative disorders involved glutamate excitotoxicity [100].

COX-2 inhibitors as a therapeutic drug for the neuronal loss after KA treatment have been studied [57]. Selective COX-2 inhibitors, for example, celecoxib, rofecoxib, NS398, and SC58125, can suppress the synthesis of PGE(2), whereby blocking hippocampal neuronal death [10, 58]. Free radical scavengers (FRSs) are known to prevent neuronal loss induced by excitotoxins [101, 102]. Edaravone (Ed), a newly developed FRS [103], and melatonin, the pineal secretory product [104], were potent to attenuate KA-induced neuronal death, suppress lipid peroxidation, and inhibit microglial activation. Sinapic acid (SA), a GABA (A) receptor agonist, can attenuate KA-induced hippocampal damage in mice via its anticonvulsive activity through GABA (A) receptor activation and radical scavenging activity [102]. Tetramethylpyrazine (TMP), a principal ingredient of Ligusticum wallichii Franch (a Chinese herb), can function as a reductant/antioxidant to quench ROS, block lipid peroxidation, and protect enzymatic antioxidants such as glutathione peroxidase and glutathione reductase [105]. TMP may prevent and rescue KA-induced neuronal loss via the preservation of the structural and functional integrity of mitochondria, evidenced by maintaining the mitochondrial membrane potential, ATP production, and complex I and III activities [106].

Preclinical data have suggested KARs as an attractive target for drug development. Tezampanel, a nonselective KAR inhibitor, can reduce migraine pain and other symptoms in
a clinical phase II study. This suppressive effect is probably attributable to the inhibition of KARs. Another KAR antagonist, NS1209, can alleviate refractory status epilepticus and neuropathic pain in phase II trials, but further research on this agent has been suspended [107]. Tat-GluR6-9c, a GluR6 C-terminus peptide conjugated to a Tat peptide, confers neuroprotection against neuronal death induced by KA-induced excitotoxic brain injury without perturbing KAR-mediated currents. This is mediated by its inhibition of JNK activation [15, 108, 109].

Expression of p27, a cyclin-dependent kinase inhibitor which arrests cell cycle at G1-S phase, was downregulated in the neuronal cell death caused by several reasons like glutamate toxicity [110]. It is demonstrated that reduced expression of endogenous p27 induced cell death in cultured cortical neurons by transfection of p27 small interfering RNA (siRNA) [111]. p27 may alleviate KA-induced seizure and hippocampal degeneration [112]. Early calpain activation is involved in neurotoxicity in the hippocampus after KA insults. Treatment with the calpain inhibitor MDL 28170 significantly suppressed the neurodegeneration induced by KA [113]. The roles of the activation of caspases and p21 in the process of neuronal death caused by KA insult have been reported in several studies. However, it is still unclear whether caspases and p21 are involved in KA-induced neurodegeneration, as evidence by negative and conflicting findings [114, 115].

5.1. Limitations of KA-Induced Neurodegenerative Model. Notwithstanding the advantages of KA-induced model in neurodegenerative studies, potential limitations should be recognized. KA-induced neurodegeneration in animals is an acute monophasic disorder, which differs from chronic neurodegenerative disorders in clinic. An alternative way to induce the chronic model, that is, long-term administration of KA at a lower dose, cannot mimic the pathogenesis of neurodegeneration adequately. This is evidenced by the fact that monosodium glutamate, a frequently added flavor enhancer, does not increase the incidence of neurodegenerative disorders. Despite a widespread belief that glutamate may elicit Chinese Restaurant Syndrome (CRS), migraine headache, and asthma, literature reviewing does not suggest that individuals may be uniquely sensitive to KA [116]. This might be partially explained by the dose-dependent effects of excitatory amino acids in the CNS. The implications of excitatory amino acid transmitters are complex. It may only represent one of several pathways involved in pathological cell death, but not necessarily the predominant or decisive one. Interventions targeted at glutamate excitotoxicity are promising, yet to be with caution, because iGluRs represent one of the major excitatory neurotransmitter pathways in the physiological functions of the brain, and the blockade of iGluRs might be disastrous to the CNS functions.

Moreover, mouse strains vary significantly in their sensitivity to KA-induced neurodegeneration [117]. In general, the C57BL/6, C57BL/10, and F1 C57BL/6×CBA/J strains of mice are resistant to systemic administration of KA, while the FVB/N, ICR and DBA/2 J strains are vulnerable [19]. Since intranasal administration can break the tolerance to KA in C57BL/6 mice, as demonstrated by Chen et al. [94], administration routes should be carefully selected when resistant strains are used. Thus, pilot studies are always indispensable; otherwise, the results might be confounded by the resistance.

Despite the theoretical or preclinical significance of KARs, concerns regarding the clinical prospects of drugs targeting AMPARs and KARs prevail. This is due to the fact that interference with excitotoxicity is accompanied unduly with effects on synaptic transmission. The recent discovery of proteins that anchor and interact with iGluRs promises a new strategy to cytoprotective therapy without interfering with synaptic transmission. The reason why iGluRs interactors appear more suitable as therapeutic targets than the receptors per se is that they might interfere specifically with excitotoxic pathways while leaving synaptic transmission untouched [118]. Also, the relationship between the structure and physiological functions of KARs is difficult to study in the CNS because of the large number of subunits of iGluRs, their widespread distribution, and neuronal heterogeneity [119, 120].

6. Concluding Remarks

Excitotoxicity is considered to be a major mechanism involved in cell death of various CNS diseases including neurodegenerative disorders. In the past decades, great progress has been made in elucidating excitatory signaling pathways whereas the mechanism by which excitatory amino acids and their receptors are implicated in neurodegenerative diseases remains little known. KA-mediated excitotoxicity has long been used as a model for elucidating mechanisms underlying oxidative stress and inflammation in neurodegenerative disorders. However, the routes of KA administration should be taken into account, especially for those strains resistant to conventional ways of administration.
