Abstract. A method for micropropagation of Conocarpus erectus through axillary shoot proliferation is presented. Shoot tips were excised from adult donor tree and cultured for 4 weeks on Murashige and Skoog’s (MS) medium supplemented with 3 mg L\(^{-1}\) gibberellic acid (GA\(_3\)) to induce sprouting of shoots and formation of axillary shoots. Conocarpus erectus shoots were cultured for 6 weeks on MS medium supplemented with different concentrations and combinations of plant growth regulators (PGRs) and proliferation of the shoots was monitored. The type and concentration of cytokinins applied had a significant influence on shoot proliferation responses. Supplementation with 6-benzylaminopurine (BAP) increased the rate of shoot proliferation compared with other cytokinins. The use of BAP in combination with auxins such as indole-3-butyric acid (IBA) and naphthalene acetic acid (NAA) resulted in an increased number of shoots per explant compared with treatment with BAP alone. A combination of 2 mg L\(^{-1}\) BAP and 0.5 mg L\(^{-1}\) IBA produced the highest number of axillary shoots (7.8 shoots/explant). The best rooting medium was full-strength MS medium supplemented with 1 mg L\(^{-1}\) IBA; this treatment yielded 80% rooting with an average of 3.5 roots per plantlet. All regenerated plantlets were successfully acclimatized to greenhouse conditions.

Micropropagation of Buttonwood Tree (Conocarpus erectus; Combretaceae) through axillary shoot proliferation is presented. Shoot tips were excised from adult donor tree and cultured for 4 weeks on Murashige and Skoog’s (MS) medium supplemented with 3 mg L\(^{-1}\) gibberellic acid (GA\(_3\)) to induce sprouting of shoots and formation of axillary shoots. Conocarpus erectus shoots were cultured for 6 weeks on MS medium supplemented with different concentrations and combinations of plant growth regulators (PGRs) and proliferation of the shoots was monitored. The type and concentration of cytokinins applied had a significant influence on shoot proliferation responses. Supplementation with 6-benzylaminopurine (BAP) increased the rate of shoot proliferation compared with other cytokinins. The use of BAP in combination with auxins such as indole-3-butyric acid (IBA) and naphthalene acetic acid (NAA) resulted in an increased number of shoots per explant compared with treatment with BAP alone. A combination of 2 mg L\(^{-1}\) BAP and 0.5 mg L\(^{-1}\) IBA produced the highest number of axillary shoots (7.8 shoots/explant). The best rooting medium was full-strength MS medium supplemented with 1 mg L\(^{-1}\) IBA; this treatment yielded 80% rooting with an average of 3.5 roots per plantlet. All regenerated plantlets were successfully acclimatized to greenhouse conditions.

The buttonwood tree or button mangrove (C. erectus; Combretaceae) is an evergreen tree that is capable of reaching 6–8 m with a crown spread of 6 m. The tree has gray or brown bark, leathery-green leaves, and greenish flowers in dense cone-like heads in terminal panicles (Bailey, 1976). This species is widely distributed in coastal communities in tropical America and West Africa (Tomlinson, 1986) and has been introduced to several other regions of the world. The tree is used as a residential street tree, for hedging, bonsai cultivation, and other landscaping purposes because of its attractive bark and soft foliage. The wood of C. erectus can be used as a fuel for cooking (e.g., smoking meats) and for production of charcoal, and has the potential to be exploited as a farm forestry tree for its fodder and timber uses (Ellison and Farnsworth, 1996; Hernandez and Espino, 1999). Pruning wastes from the trees have also been used to manufacture wood reinforced cement composites (Nasser et al., 2016). Addition of Conocarpus biochar to coarse-textured soils has been reported to improve soil hydro-properties (Ibrahim et al., 2017) and can also be used as a soil amendment for reducing heavy metal availability and uptake by maize (Zea mays) plants (Al-Wabel et al., 2015) and to enhance productivity in tomatoes (Lycopersicon esculentum) in salt-affected sandy soils under arid conditions (Usman et al., 2016). Conocarpus erectus has been used as traditional medicine for diabetes, diarrhea, and fever (Irvin, 1961) and has antioxidative and antibacterial properties (Abdel-Hameed et al., 2012; Ayoub, 2010). The pharmacognostic characteristics and biological activities of C. erectus have been reviewed (Bashir et al., 2015).

Conventional propagation of C. erectus is achieved through cuttings (Bush and Morton, 1969), although it is feasible to use seeds. However, although seed production may be high, many of the seeds are aborted or do not germinate (Tomlinson, 1986) and seed viability has been estimated as <12% (Hernandez and Espino, 1999; Kass et al., 2007). During the dry season, fewer than 5% of seeds germinated and only 1.6% of seedlings survived to flower after 25–28 months (Hernandez and Espino, 1999). An alternative approach to propagate C. erectus might be through tissue culture techniques that can facilitate the rapid production of propagules from species that are difficult to propagate using conventional techniques. This approach has developed rapidly in recent years and has been applied to a wide range of plant species of importance to the horticultural industry. Although C. erectus is of economic and medicinal importance, to our knowledge, tissue culture techniques has not been used to propagate this species. The aim of this study was to develop in vitro propagation of C. erectus through axillary shoot proliferation.

Materials and Methods

Plant material, surface disinfection, and culture establishment. Shoot tips, 3–5 cm long, were taken from adult buttonwood tree (>10 year old) at the reproductive stage (Fig. 1A). Explants were defoliated, washed running tap water, disinfected for 6 min in a 0.1% (v/v) mercuric chloride solution, and then for 6 min in 20% (v/v) commercial chlorox™ (5.2% sodium hypochlorite)
solution containing two to three drops of Tween 20 (polyoxyethylene–sorbitan monolaurate). After rinsing three times with sterile distilled water, the explants were cultured for 4 weeks on MS medium supplemented with 3.0 mg L⁻¹ GA₃ and 1 g L⁻¹ activated charcoal (Sigma-C6289; Sigma-Aldrich, Poole, UK) for shoot proliferation; MS medium without GA₃ served as a control.

Culture conditions. All media were supplemented with 3% (w/v) sucrose and solidified with 0.8% (w/v) agar–agar. Plant growth regulators were added before autoclaving. The medium was adjusted to pH 5.7 before autoclaving at 121 °C for 20 min. The cultures were incubated at 25 ± 2 °C under a 16-h photoperiod provided by cool-white fluorescent lights at 35 μmol m⁻² s⁻¹ photosynthetic photon flux density (PPFD).

Axillary shoot proliferation. Conocarpus erectus axillary shoots (2–3 cm with three to four nodes) were cultured on MS medium supplemented with different concentrations of BAP (0, 0.1, 0.5, 1, and 2 mg L⁻¹), kinetin (0, 1, 2, 4, and 6 mg L⁻¹), thidiazuron (TDZ; 0, 0.1, 0.5, 1, and 1.5 mg L⁻¹), NAA (0, 0.1, 0.5, and 1.0 mg L⁻¹), and IBA (0, 0.1, 0.5, and 1.0 mg L⁻¹). Shoot growth and proliferation responses in terms of number of axillary shoots per explant, shoot length, and fresh weight of whole explants were recorded after 6 weeks of culture. All measurements were obtained from 10 randomly chosen shoots. The environment in the growth chamber was adjusted to a 25 ± 2 °C air temperature, 50% to 60% relative humidity, and 100 μmol·m⁻²·s⁻¹ PPFD with a 16-h photoperiod using halide lamps.

Experimental design and data analysis. The experiments were performed using a completely randomized design. Data on rooting were expressed as percentages and then arc sine transformed before analysis (Compton, 1994). All data were subjected to Duncan’s multiple range test and analysis of variance using the SAS program Version 6.12 (SAS Institute Inc., Cary, NC).

Results and Discussion

Establishment of C. erectus aseptic culture. Oxidative browning was a major problem during the initiation of culture of C. erectus shoot tips (Fig. 1B). Tissue browning occurs because of the accumulation and subsequent oxidation of phenolic compounds in the tissue and in the culture medium (Krishna et al., 2008; Uchendu et al., 2011). Oxidative browning causes slow growth, low regeneration, and eventually leads to cell/tissue or plant death (Krishna et al., 2008; Panaia et al., 2000) and has been reported to hinder the establishment of cultures in several woody plant species such as Platanus occidentalis (Tao et al., 2007) and Arbutus unedo (El-Mahrouk et al., 2010). In the present study, soaking of explants in an antioxidant solution, the addition of activated charcoal to the medium, and avoiding the use of ethanal during surface disinfection prevented tissue browning (Fig. 1C; data not presented). Activated charcoal is an adsorbent that binds phenolic compounds and renders them less toxic (Thomas, 2008). The use of antioxidant solutions has been employed to reduce or prevent browning in plant tissue cultures (Tao et al., 2007; Toth et al., 1994; Uchendu et al., 2011). Conocarpus erectus
explants developed axillary shoots on MS medium without PGRs but addition of 3 mg·L⁻¹ GA₃ accelerated their proliferation and growth. The proliferating shoots were healthier and had no browning compared with shoots on medium without GA₃ (data not presented). GA₃ has been reported to regulate expression of the gene for phenylalanine ammonia-lyase (PAL; EC 4.3.1.5) and to reduce the activity of the PAL enzyme; as a consequence, the addition of GA₃ to the medium was found to reduce browning in *Phalaenopsis* tissue culture (Zhou et al., 2009). A novel approach to reduce oxidative browning was described in culture of *Artemisia annua* through the incorporation of an inhibitor of PAL activity, 2-aminoindan-2-phosphonic acid, into the culture medium (Jones and Saxena, 2013). A novel approach to reduce oxidative browning was described in culture of *Artemisia annua* through the incorporation of an inhibitor of PAL activity, 2-aminoindan-2-phosphonic acid, into the culture medium (Jones and Saxena, 2013). A novel approach to reduce oxidative browning was described in culture of *Artemisia annua* through the incorporation of an inhibitor of PAL activity, 2-aminoindan-2-phosphonic acid, into the culture medium (Jones and Saxena, 2013).

**Axillary shoot proliferation.** Axillary shoot proliferation, shoot length, and fresh weight of *C. erectus* explants were significantly influenced by cytokinins type and concentration (Table 1; Fig. 1D and E). Supplementation of medium with 1.0 and 2.0 mg·L⁻¹ BAP induced the highest number of axillary shoots (3.5 and 4 per explant, respectively) compared with other treatments. Kinetin did not stimulate shoot proliferation. MS medium without PGRs had the lowest number of shoots, smallest shoot lengths, and lowest fresh weight per explants. In general, BAP had a greater effect than TDZ or kinetin for shoot proliferation, whereas 4 mg·L⁻¹ kinetin resulted the greatest shoot lengths (Table 1). The superiority of BAP over other cytokinins for the induction of shoot proliferation in culture has been demonstrated previously in other woody plant species, including *Pittosporum napaulensis* (Dhar et al., 2000) and *Lessertia frutescens* (Shaik et al., 2010), and in other members of the family Combretaceae such as *Terminalia arjuna* (Pandey et al., 2006) and *Terminalia bellerrica* (Dangi et al., 2014). *Conocarpus erectus* shoots cultured on medium containing 0.1 mg·L⁻¹ TDZ produced an average of 3.2 shoots per explant; however, the rate of proliferation was reduced with increasing TDZ concentration (Table 1). TDZ has been shown to be an effective and potent synthetic cytokinin for shoot organogenesis and morphogenesis in many plant species, including woody plants (Heutteman and Preece, 1993; Murthy et al., 1998). However, in the present study, TDZ was not effective for shoot proliferation in *C. erectus*; indeed, abnormal morphology and stunted growth was associated with all TDZ treatments. Calluses also formed at the base of proliferating shoots. TDZ has been shown to be ineffective in plant species such as *Spathiphyllum cannifolium* (Dewir et al., 2006) and *Fraxinus excelsior* (Mitras et al., 2009), i.e., it has species specific effects. The abnormalities induced by TDZ depended on the concentration and the duration of treatment. Various BAP and IBA or NAA combinations were tested for induction of axillary shoots (Fig. 2A–C), and the results indicated that MS medium containing 2.0 mg·L⁻¹ BAP and 0.5 mg·L⁻¹ IBA had the highest rate of shoot proliferation (7.8 shoots per explant) compared with other combinations. It has been reported that combination of BAP and auxins may result in a synergistic increase in shoot proliferation, as in woody plant species, including *T. arjuna* (Pandey et al., 2006), *A. unedo* (El-Mahrouk et al., 2010), and *L. frutescens* (Shaik et al., 2010).

**In vitro rooting and acclimatization.** Varying medium strength and auxin concentrations significantly influenced rooting of *C. erectus* (Table 2). The best rooting medium was full-strength MS supplemented with 1 mg·L⁻¹ IBA; this treatment induced root formation in 80% of the explants with an average of 3.5 roots per explant and an average root length of 5.9 cm (Table 2; Fig. 3A). No rooting occurred in full-strength MS medium without...
auxins, whereas half-strength MS medium resulted in 20% rooting, indicating that a reduced salt concentration stimulated rooting. Improved rooting under reduced salt concentrations has been suggested to be due to the reduction in nitrogen content rather than a change in osmotic potential (Hyndman et al., 1982). Auxin type and concentration significantly influenced the rate of rooting, the average number of roots, and explant fresh weight. Higher concentrations of auxins (≥1 mg L\(^{-1}\)) proved unfavorable to rooting because of callus formation at shoot bases. Low rooting ability is a limiting factor in the micropropagation of woody plant species (Dewir et al., 2011; Nemeth, 1986). Our results confirm previous findings on in vitro rooting of *Parkia timoriana* (Thangjam and Sahoo, 2012) and *Syzygium cordatum* (Dewir et al., 2011) in which rooting was dependent on medium strength, and the type and concentration of auxins. In an attempt to increase the rate of rooting in *C. erectus*, different sucrose concentrations and application of activated charcoal were tested; none of the tested treatments increased the rate of rooting (data not presented). A high sucrose level (5%) reduced the rate of rooting (to 40%), whereas a 1% sucrose concentration did not alter the rate of rooting. The addition of activated charcoal to the rooting medium did not increase the rate of rooting; however, it did enhance early root initiation, which was observed after 7 d of culture (Fig. 3B; data not presented). This effect of activated charcoal might be a result of its ability to irretrievably adsorb inhibitory compounds in the culture medium (Thomas, 2008). Regenerated plantlets of *C. erectus* were acclimatized to ex vitro conditions (Fig. 3C).

In conclusion, an efficient micropropagation protocol for *C. erectus* was developed. Tissue browning was overcome through soaking of explants in antioxidans solution, avoiding the use of ethanol during surface disinfection, and the addition of 1 g L\(^{-1}\) activated charcoal and 3 mg L\(^{-1}\) GA\(_3\) to the initiation medium. The highest rate of shoot proliferation (7.8 shoots per explant) was recorded in MS medium with 2 mg L\(^{-1}\) BAP and 0.5 mg L\(^{-1}\) IBA. Root proliferation occurred in 80% of explants in full-strength MS medium supplemented with 1 mg L\(^{-1}\) IBA and successfully acclimatized to ex vitro conditions.

### Table 2. Effect of medium salt strength and auxin concentrations on rooting of *Conocarpus erectus* after 4 weeks in culture.

| Medium salt strength | Auxins (mg L\(^{-1}\)) | Rooting (%) | Roots (no./explant) | Root length (cm) | Fresh wt per plantlet (g) |
