ABSTRACT

We present 1.3 mm ALMA Cycle 0 observations of the edge-on debris disk around the nearby, ∼10 Myr old, M-type star AU Mic. These observations obtain 0′′.6 (6 AU) resolution and reveal two distinct emission components: (1) the previously known dust belt that extends to a radius of 40 AU and (2) a newly recognized central peak that remains unresolved. The cold dust belt of mass ∼1 M_{Moon} is resolved in the radial direction with a rising emission profile that peaks sharply at the location of the outer edge of the “birth ring” of planetesimals hypothesized to explain the midplane scattered light gradients. No significant asymmetries are discerned in the structure or position of this dust belt. The central peak identified in the ALMA image is ∼6 times brighter than the stellar photosphere, which indicates an additional emission process in the inner regions of the system. Emission from a stellar corona or activity may contribute, but the observations show no signs of temporal variations characteristic of radio-wave flares. We suggest that this central component may be dominated by dust emission from an inner planetesimal belt of mass ∼0.01 M_{Moon}, consistent with a lack of emission shortward of 25 μm and a location ≤3 AU from the star. Future millimeter observations can test this assertion, as an inner dust belt should be readily separated from the central star at higher angular resolution.

Key words: circumstellar matter – planet–disk interactions – stars: individual (AU Microscopii) – submillimeter: planetary systems

Online-only material: color figures

1. INTRODUCTION

Debris disks are created by the collisional erosion of planetesimals, the building blocks of planetary systems. These collisions continuously generate dust grains with a range of sizes that are detected with astronomical measurements from optical to radio wavelengths. Resolved observations of nearby debris disks are instrumental in advancing our understanding of these systems. At a distance of 9.91 ± 0.10 pc (van Leeuwen 2007), the M1 star AU Mic hosts one of the closest and best studied debris disks. The detection of submillimeter emission (Liu et al. 2004) from this ∼10 Myr old system in the β Pic moving group (Zuckerman et al. 2001) was followed quickly by the discovery of an edge-on disk seen in scattered starlight (Kalas et al. 2004). Subsequent work has characterized the scattered light in great detail, exploiting its proximity to constrain its radial and vertical structure (Liu 2004; Krist et al. 2005; Metchev et al. 2005; Graham et al. 2007; Fitzgerald et al. 2007).

Observations of dust emission at (sub)millimeter wavelengths provide important, complementary information about debris disk structures. Unlike the small grains probed at optical and near-infrared wavelengths that react strongly to stellar radiation and wind forces, the large grains that dominate the millimeter-wave emission have dynamics more like the parent planetesimals. As a result, long-wavelength images trace best the location and distribution of the larger colliding bodies (Wyatt 2006), and potentially also the signatures of planets that interact with them (Ertel et al. 2012). These size-dependent dust dynamics manifest beautifully in the edge-on AU Mic disk. Resolved millimeter-wave observations show an emission belt within the extended optical disk that peaks near a radius of 35 AU, where the midplane scattered light profile steepens dramatically (Wilner et al. 2012). These features are elegantly explained by the presence of a “birth ring” of planetesimals at that location, where small grains released in a collisional cascade are launched into an extended halo (Strubbe & Chiang 2006; Augereau & Beust 2006).

With the advent of the Atacama Large Millimeter Array (ALMA), the millimeter emission in nearby debris disks can be imaged in much greater detail (e.g., Boley et al. 2012). In this Letter, we present new, subarcsecond resolution ALMA Cycle 0 observations of AU Mic at λ = 1.3 mm. The ALMA data provide substantially improved constraints on the locations of colliding planetesimals in the AU Mic disk and help shed light on the processes that may be shaping the planetesimal distribution. They also reveal a previously unknown, centrally located emission feature.

2. OBSERVATIONS

AU Mic was observed by ALMA with its Band 6 receivers over four 2 hr long “scheduling blocks” (SBs) in 2012 April and June. Table 1 summarizes the observations. The 16–20 operational 12 m antennas were arranged to span baseline lengths of
21–402 m (corresponding to a maximum resolution of ~0.6).

The correlator was configured to optimize continuum sensitivity, processing two polarizations in four 2 GHz-wide basebands, each with 128 spectral channels, centered at 226, 228, 242, and 244 GHz. In each SB, we interleaved observations of AU Mic (pointing center $\alpha = 20^h45^m09.34$, $\delta = -31^\circ20'24.09$, J2000, within 1″ of the star position at all epochs) with the nearby quasar J2101−295.

The data from each SB were calibrated independently within the CASA software package. After applying system temperature measurements and phase corrections from the water vapor radiometers, the data were flagged and averaged into 6.048 s integrations. A calibration of the spectral response of the system was derived from observations of Neptune: a mean calibration was applied to all basebands, with a systematic uncertainty of the mean calibration. The flux calibration was derived from observations of J2101−295, within 1″ of the star position at all epochs) with the nearby quasar J2101−295.

The data were corrected using observations of J2101−295, and complex gain variations induced by atmospheric and instrumental effects were corrected using observations of J2101−295. The absolute flux calibration was derived from observations of Neptune: a mean calibration was applied to all basebands, with a systematic uncertainty of ~10% (see Section 3.3). To generate an image at the mean frequency, 235 GHz (1.28 mm), we Fourier inverted the calibrated visibilities with natural weighting and performed a multi-frequency synthesis deconvolution with the CLEAN algorithm. The visibilities were further reduced by spectrally averaging over the central 112 channels in each baseband and re-weighted by the observed scatter.

### 3. RESULTS AND ANALYSIS

#### 3.1. Image of 1.3 mm Dust Continuum Emission

Figure 1 shows an image of the $\lambda = 1.3$ mm emission from SB-4 (with the most antennas and best weather conditions), with synthesized beam 0′.80 × 0′.69 (8 × 7 AU), position angle (P.A.) $49^\circ$, and an rms of 30 μJy beam$^{-1}$. An image constructed from all four SBs is consistent but noisier, which we attribute to systematic calibration issues resulting from the poorer weather conditions of the earlier observations. The emission is confined to a narrow band with a aspect ratio > 10:1, with an orientation consistent with the scattered light disk. The emission is not resolved in the direction perpendicular to the elongation. There are clear peaks near both extrema and in the middle of the structure (detected at all four epochs). The emission is marginally brighter at the northwest end than the southeast end, and shows small undulations along its length, though none of these variations are significant. We interpret the observed structure as a superposition of two components: (1) the nearly edge-on dust belt with limb-brightened ansae and (2) a new, distinct, and compact feature located at the center of the belt.

#### 3.2. Modeling Formalism

Building on the phenomenological methodology of Wilner et al. (2011, 2012) to analyze resolved millimeter emission from debris disks, we construct a parametric model to quantify the observed properties of the AU Mic emission. We consider two model components: a vertically thin, axisymmetric “outer” belt and an additional source to account for the central peak. The belt component is informed by models of the scattered light that show the disk midplane within 50 AU is remarkably straight, <0.5′ from edge-on, and thin (FWHM ~ 0.3). We assume that the belt is viewed at an inclination of 89.5. The belt is characterized as an annulus with (unprojected) radial intensity $I_\nu(r) \propto r_\alpha$ for $r_t < r < r_o$, with a normalization defined by $F_{\text{belt}} = \int I_\nu d\Omega$, a center determined by offsets (relative to the pointing center) {Δ$\alpha$, Δ$\delta$}, and an orientation described by a P.A. We treat the central component as a circular Gaussian with mean $\Delta\alpha_{\text{cen}}$, variance $\sigma^2_{\text{cen}}$ (half-width at half-maximum $R_{\text{cen}} = \sqrt{2 \ln 2} \sigma_{\text{cen}}$), and flux density $F_{\text{cen}}$. The mean Δ$\alpha_{\text{cen}}$ is defined as a radial shift from the belt center in the plane of the belt. We also include power-law spectral scalings between the four basebands for each component, denoted $\alpha_{\text{belt}}$ and $\alpha_{\text{cen}}$, where $F_\nu \propto \nu^{-\alpha}$.

For a given parameter set, we compute four synthetic visibility sets sampled at the same spatial frequencies observed by ALMA, corresponding to the spectrally averaged basebands (at 226, 228, 242, and 244 GHz). By fitting the visibility data directly, we are not sensitive to the non-linear effects of deconvolution, and take advantage of the full range of available spatial frequencies. The fit quality is quantified by a likelihood metric, $\mathcal{L}$, determined from the $\chi^2$ values summed over the real and imaginary components at all spatial frequencies (In $\mathcal{L} = -\chi^2/2$). A Monte Carlo Markov Chain (MCMC) approach was utilized to characterize the multi-dimensional parameter space of this model and determine the posterior probability distribution functions for each parameter. We used the affine-invariant ensemble sampler proposed by Goodman & Weare (2010), in a locally modified version of the parallelized implementation described by Foreman-Mackey et al. (2012), to compute likelihood values for ~10$^6$ MCMC trials. Uniform priors were assumed for all parameters, with bounds imposed to ensure that the model was well defined: { $F_{\text{belt}}$, $F_{\text{cen}}$, $\sigma^2_{\text{cen}}$ } $\geq$ 0, and 0 $\leq$ $r_t$ $<$ $r_o$. 

### Table 1

| ID   | Date (UT) | Antennas | PWV (mm) |
|------|-----------|----------|----------|
| SB-1 | 2012 Apr 23 07:30–09:26 | 17 | 1.7 |
| SB-2 | 2012 Apr 23 09:39–11:03 | 16 | 1.7 |
| SB-3 | 2012 Apr 24 09:09–11:19 | 18 | 3.0 |
| SB-4 | 2012 Jun 16 05:48–08:02 | 20 | 0.7 |

(A color version of this figure is available in the online journal.)
3.3. Results of Model Fits

The best-fit parameter values and their 68% uncertainties determined from the marginalized posterior probability distributions are listed in Table 2. The data and best-fit model are compared in the image plane in Figure 2; there are no significant residuals. The best-fit model has a reduced $\chi^2 = 1.37$ (905, 920 independent data points, 12 free parameters). The modeling procedure was performed on each SB individually and the full data set (all four SBs together). The results were entirely consistent, although the parameter uncertainties were notably smaller from the superior SB-4 data set alone, and we focus on those results.

Most parameters are determined with high precision. We find good agreement of the outer belt parameters $\{F_{\text{belt}}, r_i, r_o\}$ with the less well-constrained fits of Wilner et al. (2012), and on the disk P.A. from measurements of scattered starlight (e.g., Krist et al. 2005). We measure a flat spectrum for the outer belt ($\alpha_{\text{belt}} \approx 0$) across the four basebands, which corresponds to the difference between the spectral slopes of AU Mic and Neptune ($\alpha_{\text{Neptune}} \approx 2.1$), consistent with data from 350 $\mu$m to 1.3 mm (Wilner et al. 2012).

The central emission peak is detected with high confidence at $F_{\text{cen}} = 320 \mu$Jy ($>10\sigma$ brighter than the outer belt at that location). It is unresolved, with $R_{\text{cen}} \leq 3.0$ AU ($3\sigma$), and positionally coincident with the outer belt center: $\Delta r_{\text{cen}} \leq 1.9$ AU ($3\sigma$). Regarding the outer belt, the most notable result is that the models strongly favor rising emission profiles with large, positive gradients: $x \approx 2.3 \pm 0.3$. Models with the standard assumption of $x < 0$ produce significant residuals, underpredicting the intensities at $\pm 1^\circ - 2^\circ$ from the belt center. Because of the steep increase in the emission profile, there is only a weak constraint on the inner edge of the outer belt. The best-fit $r_i$ deviates from 0 at the $\sim 2\sigma$ level: the $3\sigma$ limit is $r_i \leq 21$ AU.

4. DISCUSSION

We have presented new, subarcsecond resolution ALMA observations of 1.3 mm emission from the AU Mic debris disk and analyzed the data with a simple parametric model. This emission is resolved into two distinct components: (1) an edge-on outer belt with an emission profile that rises with radius out to 40 AU, and (2) an unresolved peak at the center of the outer belt. This distribution is more complex than the single, narrow ring often assumed for debris disks. However, it has some similarities to other nearby resolved systems, such as $\epsilon$ Eri (Backman et al. 2009) or HR 8799 (Su et al. 2009), that show an inner component inferred from excess infrared emission, separate from an extended and colder outer belt.

4.1. The Central Emission Peak

The stellar photosphere is much fainter than the central peak noted in Figure 1. A NextGen stellar model (Hauschildt et al. 1999) with $T_{\text{eff}} = 3720$ K, $L_\star = 0.11 L_\odot$, and $M_\star = 0.6 M_\odot$ (e.g., Metchev et al. 2005; Chen et al. 2005) that matches the AU Mic photometry from 0.4 to 25 $\mu$m contributes only $F_\star = 52 \mu$Jy at 1.3 mm, $\sim 6$ times fainter than observed. However, AU Mic is an active star that exhibits radio-wave bursts. In quiescence, observations find $<120 \mu$Jy at 3.6 cm (White et al. 1994), and the contribution at 1.3 mm from hot coronal plasma seen in X-rays is unlikely to be significant (though better spectral constraints are desirable; see Leto et al. 2000). Flares are detected from AU Mic at $\sim 200$–$1200 \mu$Jy at 6 cm (Bower et al. 2009), but this non-thermal emission is much weaker at 1.3 mm. While the unknown variability makes any extrapolation to 1.3 mm problematic, the temporal properties...
of the ALMA emission provide additional information. Radio-wave flares have fast decay times, of the order of an hour (Kundu et al. 1987); but, the mm-wave peak persists at a consistent intensity in all four ALMA observations, within uncertainties that are typically 2–3 times larger than for SB-4, spanning timescales from 1 hr (within SB-4) to two months (SB-1 to SB-4). Unfortunately, the spectral index ($\alpha_{cen}$) constraints are not good enough to be diagnostic. We suspect that stellar emission is too weak and too ephemeral to be responsible for the 1.3 mm peak, but the available data do not allow for a firm determination of its contribution.

Alternatively, the central emission peak could be produced by dust in a distinct (unresolved) planetesimal belt located close to the star. In Section 3.3, we constrained the extent of this peak to $R_{cen} \lesssim 3$ AU ($3\sigma$), inside the inner working angle ($0.8 \approx 8$ AU) of all previous high-resolution imaging of scattered light (Krist et al. 2005; Fitzgerald et al. 2007).

Rough models of the spectral energy distribution (SED) from the ALMA central peak can help assess the feasibility that it originates in an inner dust belt. In this context, the most salient angle ($0.8$ cm) constraints are not good enough to be diagnostic. We suspect that stellar emission is too weak and too ephemeral to be responsible for the 1.3 mm peak, but the available data do not allow for a firm determination of its contribution.

Adopting the opacity used in Section 4.1 ($\kappa_\nu = 2.7$ cm$^2$ g$^{-1}$), and assuming $T \approx 25$ K (for 35–45 AU), the dust mass of this outer belt is $7 \times 10^{25}$ g (consistent with previous estimates; Liu et al. 2004), $\sim 100$ times more massive than the hypothesized inner belt; the Kuiper Belt and asteroid belt have a similar mass ratio.

The mm-wave emission morphologies of cold belts of dusty debris reflect the dynamical processes that shape the underlying planetesimal distributions. For AU Mic, our modeling suggests that its outer emission belt can be described by an increasing emission profile with a positive radial power-law index $x \approx 2.3 \pm 0.3$. If we assume the emitting dust is in radiative equilibrium with a temperature profile $T \propto r^{-0.5}$, this implies a rising surface density profile, $\Sigma \propto r^{2.8}$, strongly peaked near 40 AU. A broad parent body ring with constant surface density would produce a radial intensity profile with $x \approx -0.5$, a value ruled out with high confidence ($>5\sigma$). A rising behavior is predicted for “self-stirred” disks with ongoing planet formation (Kenyon & Bromley 2002); in particular, the models of Kennedy & Wyatt (2010) suggest $\Sigma \propto r^{1.5}$. However, the timescale required to assemble Pluto-sized bodies at $\sim 40$ AU to initiate a collisional cascade around a low-mass star like AU Mic is much longer than its $\sim 10$ Myr age (Kenyon & Bromley 2008). Moreover, this scenario does not naturally accommodate the presence of a separate, interior planetesimal belt. Of course, the still modest resolution of the data is compatible with more complex scenarios, such as multiple closely spaced belts of different brightnesses that mimic a smooth gradient. Scattered light observations of the AU Mic disk show asymmetries on both large and small scales, with several peaks and depressions projected against the broad ansae in Figure 1, radii beyond the millimeter undulations (features A–E; see Fitzgerald et al. 2007). With such a steep emission gradient in this outer belt, the data do not strongly constrain its width, or the location of its inner edge. Our modeling indicates substantial emission from mm sized grains interior to 40 AU, in the ∼20–40 AU zone inferred to be highly depleted of $\mu$ m sized grains from polarized scattered light (Graham et al. 2007).

The ALMA data show no clear evidence for asymmetries or substructure that would signal planet–disk interactions. The hints of modulating millimeter brightness along the belt in Figure 1 are insignificant in the residuals from subtracting a symmetric parametric model (see Figure 2). This rules out substructure brighter than $9\sigma$ beam$^{-1}$ ($3\sigma$), corresponding to dust clumps $\gtrsim 1\%$ of the lunar mass (for the dust properties adopted above). Those limits argue against overdensities of dust-producing planetesimals trapped in mean motion resonances (Kuchner & Holman 2003), as might arise from the outward migration of planets (Wyatt 2003). Given the young age of the system, the broad and smooth character of the outer belt in the AU Mic disk may resemble the Kuiper Belt prior to the epoch of Neptune’s migration (Malhotra 1995). It is interesting that none of the claims of millimeter emission clumps in debris disks have survived scrutiny at higher sensitivity (Piétu et al. 2011; Hughes et al. 2011, 2012). It may be that any such features are effectively erased by collisions (Kuchner & Stark 2010). We also find no significant centroid offset between the outer belt and central peak, as might result from the secular perturbations of a planet in an eccentric orbit (Wyatt et al. 1999). The limit on the displacement, $\Delta_{cen} < 1.9$ AU ($3\sigma$), corresponds approximately to a limit on $ae$, where $a$ is the semimajor axis and $e$ is the eccentricity. This limit can still accommodate a wide-orbit planet with modest eccentricity, similar to Uranus. Such a planet...
could be responsible for stirring the disk to 40 AU in ~10 Myr (e.g., for $a = 30$ AU and $e = 0.05$, see Equation (15) of Mustill & Wyatt 2009). Limits from high contrast direct imaging admit Saturn-mass planets at these separations (Delorme et al. 2012).

4.3. Concluding Remarks

The basic architecture of the AU Mic debris disk appears remarkably similar to the solar system, with a potential analog to the asteroid belt at a few AU, and a colder, more massive, and apparently truncated counterpart of the Kuiper Belt extending to 40 AU. Future observations are needed to determine if stellar processes could be responsible for emission attributed to the asteroid belt, and to determine if the solar system analogy extends to include a planetary system like our own.
