Hanbury Brown-Twiss Effect with Wave Packets

The Hanbury Brown-Twiss (HBT) effect is essentially a quantum interference of one particle with another, as opposed to interference of a particle with itself. Conventional treatment of identical particles, especially when they are entangled, is marred by attaching labels to the particles which appears contradictory. A recently introduced label-free approach to indistinguishable particles is described, and is used to analyze the HBT effect. Quantum wave-packets have been used to provide a better understanding of the quantum interpretation of the HBT effect. The effect is demonstrated for two independent particles governed by Bose-Einstein or Fermi-Dirac statistics. The HBT effect is also analyzed for pairs of entangled particles. Surprisingly, entanglement has almost no effect on the interference seen in the HBT effect. In the light of the results, an old quantum optics experiment is reanalyzed, and it is argued that the interference seen in that experiment is not a consequence of non-local correlations between the photons, as is commonly believed.

I. INTRODUCTION

Interference of waves is a very old and well studied subject. Waves emanating from two sources give rise to interference, provided that there is a coherence in the phases of the two. This can be understood with the following argument. Suppose there are two sources A and B, waves emerging from which fall on a distant screen. At a point $x_1$ on the screen, the contribution of the two classical waves can be written as

$$E(x_1) = \alpha e^{ikr_{A1}} + \beta e^{ikr_{B1} - i\phi},$$

where $k$ is the wave-vector of the two waves, $r_{A1}, r_{B1}$ are the displacements as shown in Fig. 1, and $\phi$ is the difference in the phases of the two sources. Assuming $\alpha, \beta$ to be real, the intensity at the point $x_1$ is then given by

$$I(x_1) \equiv |E(x_1)|^2 = \alpha^2 + \beta^2 + 2\alpha\beta \cos(k(r_{A1} - r_{B1}) + \phi).$$

The above expression represents interference between the wave from A and B, at point $x_1$ on the screen. One can see that if the phase difference between the two waves, $\phi$, fluctuates randomly with time, which amounts to integrating the above over $\phi$, the interference will be washed away.

$$\langle I(x_1) \rangle \approx \alpha^2 + \beta^2.$$  \hspace{1cm} (3)

Thus two independent, incoherent sources of waves do not give rise to interference.

Hanbury Brown and Twiss carried out an experiment with radio waves which involved correlating intensities at two points on the screen, coming from two independent sources [1]. Their experiment can be easily understood from the preceding example. An intensity correlation at two points $x_1$ and $x_2$ on the screen can be written as

$$I(x_1)I(x_2) = |E(x_1)|^2|E(x_2)|^2 = \left\{ \begin{array}{l}
\alpha^2 + \beta^2 + 2\alpha\beta \cos(k(r_{A1} - r_{B1}) + \phi) \\
\alpha^2 + \beta^2 + 2\alpha\beta \cos(k(r_{A2} - r_{B2}) + \phi) \end{array} \right.$$  \hspace{1cm} (4)

After averaging over $\phi$, the $\phi$-dependent terms drop out, and one is left with

$$\langle I(x_1)I(x_2) \rangle \approx (\alpha^2 + \beta^2)^2 + 2(\alpha\beta)^2 \cos(k(r_{A1} - r_{B1} - r_{A2} + r_{B2})).$$ \hspace{1cm} (5)

Surprisingly, although individual intensities do not show any oscillation, there is interference between the intensities at two different points on the screen. This is what is called the Hanbury Brown-Twiss (HBT) effect. Random fluctuation of phases of the independent source has no effect on the oscillations seen in the intensity correlations. Notice that the visibility [2] of the above interference pattern is $\frac{2(\alpha\beta)^2}{(\alpha^2 + \beta^2)^2}$ which is bounded from above by 1/2.

The HBT effect was explained using classical waves, but when the same experiment was proposed using light, there was a lot of skepticism, and people thought it would not work. The reason was that the HBT effect arose from two different waves interfering with each other, and many people believed that a photon interferes only with itself, two photons never interfere with each other [3]. Hanbury Brown and Twiss carried out the experiment with light and demonstrated the HBT effect [4]. The first quantum understanding of the HBT effect for light was given by Fano [5]. The HBT effect has now been demonstrated for quantum light [6]. Not only that, it has also been demonstrated with massive particles, both of bosonic [7–9] and fermionic [10] nature.

The HBT effect for massive particles is intriguing, as it involves interference between two different particles. Particles are seen to be bunched together without any interaction between them. It is a purely quantum mechanical effect, and the classical wave explanation is only a part of the story. Full treatment of the HBT effect can of course be done using quantum many-body theory, as the particles are treated as being indistinguishable there. However, that maybe an overkill, as it is essentially a two particle effect. In the following we treat two massive particles as traveling wave-packets, and use them to analyze the HBT effect.

II. LABEL-FREE APPROACH TO IDENTICAL PARTICLES

For a quantum treatment of the HBT effect, it is essential to take the indistinguishability of the particles into account. However, treatment of identical particles in quantum mechanics, particularly those involving entanglement, has been an issue which has been much debated [11–29]. The problem can be seen in the very basic symmetric or anti-symmetric wavefunctions that are usually written, e.g., \( \phi_A(x_1)\phi_B(x_2) \pm \phi_B(x_1)\phi_A(x_2) \). Although the particles are assumed to be indistinguishable, we put labels 1 and 2 on them. The problem gets compounded when one wants to write an entangled state for two such particles. Recently a new state-based approach has been introduced which does not label the particles [30]. In the following, we will explain this approach and use it to analyze HBT experiment with quantum particles.

In this new approach, the basic assumption is that in dealing with more than one identical particles, the particles cannot be individually addressed. This is in accordance with the quantum theory. The combined state of two particles, which may consist of single-particle states, is treated as a holistic indivisible entity [30]. One cannot ask for the form of this state. What one can ask is, what is the two particle probability amplitude of finding the two particles in two different states is. For example, if one particle is in the single-particle state \( |\psi\rangle \) and one in the state \( |\phi\rangle \), the two-particle state is represented as \( |\phi, \psi\rangle \). One may not talk about the “form” of this state in terms of single-particle states \( |\psi\rangle \) and \( |\phi\rangle \). However, the probability amplitude of finding one particle in state \( |\alpha\rangle \) and the other in state \( |\beta\rangle \), i.e., in the combined state \( |\alpha, \beta\rangle \), is given by

\[
\langle \alpha, \beta | \phi, \psi \rangle = \langle \alpha | \phi \rangle \langle \beta | \psi \rangle + \eta \langle \alpha | \psi \rangle \langle \beta | \phi \rangle,
\]

where \( \eta^2 = 1 \). One can check that the state \( |\phi, \psi\rangle \) is not normalized simply by replacing \( |\alpha, \beta\rangle \) by \( |\phi, \psi\rangle \) in the above equation. The state \( |\phi, \psi\rangle \) has to be multiplied with \( \frac{1}{\sqrt{1 + \eta^2}} \) in order to normalize it. The probability amplitude of finding the particles at positions \( x_1 \) and \( x_2 \), i.e., in the state \( |x_1, x_2\rangle \) is given by

\[
\langle x_1, x_2 | \phi, \psi \rangle = \langle x_1 | \phi \rangle \langle x_2 | \psi \rangle + \eta \langle x_1 | \psi \rangle \langle x_2 | \phi \rangle,
\]

which is the familiar symmetric or antisymmetric two-particle wavefunction. The difference is that, in this case 1 and 2 are not labels of particles, but corresponds to the two positions of a joint measurement.

A one-particle operator \( A \) acts on the two-particle state in the following way:

\[
A|\phi, \psi\rangle = |A\phi, \psi\rangle + |\phi, A\psi\rangle.
\]

The expectation value of a one-particle operator, using (6) and (8), is given by

\[
\langle A \rangle = \langle \phi | \psi \rangle \langle A | \phi, \psi \rangle = \langle \phi | A\phi \rangle + \langle \psi | A\psi \rangle + \eta (\langle \phi | \psi \rangle \langle A | \phi \rangle + \langle \psi | \phi \rangle \langle A | \psi \rangle),
\]

which agrees with the expression of the conventional analysis.

III. INDEPENDENT PARTICLES

Let there be two particles described by two wave packets, traveling along y-axis. The two particles emerge from two sources localized at positions \( x_0 \) and \( -x_0 \). We described the two particles by two Gaussian wave packets of width \( \epsilon \) each, localized at \( x_0 \) and \( -x_0 \), denoted by \( |\phi_A\rangle \) and \( |\phi_B\rangle \), respectively. Since the particles are indistinguishable, the combined initial state of the two particles can be written as

\[
|\psi(0)\rangle = |\phi_A, \phi_B\rangle
\]

This satisfies the essential requirement for HBT effect, that the particles be identical, in the quantum sense. The conventional two-particle wavefunction is then just the probability amplitude of finding one particle at \( x_1 \) and one at \( x_2 \), and can be written down using (6) as follows:

\[
\langle x_1, x_2 | \phi, \psi \rangle = \langle x_1 | \phi_A \rangle \langle x_2 | \phi_B \rangle + \eta \langle x_1 | \phi_B \rangle \langle x_2 | \phi_A \rangle = \frac{1}{\sqrt{\pi \epsilon}} \left( e^{-\frac{(x_1-x_0)^2}{\epsilon^2}} e^{-\frac{(x_2-x_0)^2}{\epsilon^2}} + \eta e^{-\frac{(x_1+x_0)^2}{\epsilon^2}} e^{-\frac{(x_2+x_0)^2}{\epsilon^2}} \right)
\]

(11)
where $\eta = \pm 1$. The last line in the above equation specifies the Gaussian form of the states emerging from the sources A and B, namely, $\phi_A(x) = \exp^{-\frac{(x-x_0)^2}{\Delta^2}}$ and $\phi_B(x) = \exp^{-\frac{(x+x_0)^2}{\Delta^2}}$. For bosonic particles, the wavefunction should be antisymmetric, and $\eta$ should be 1. For fermions, the two-particle wavefunction should be asymmetric, requiring $\eta$ to be $-1$. We assume that the particles are traveling along the positive y-direction with a constant velocity $v_0$. For simplicity we ignore the explicit time evolution along the y-axis, and assume that evolution for a time $t'$ just transports the wave packets by a distance $l = v_0 t'$. The dispersion of the wave packets along the transverse x-direction is more interesting and may give rise to interference between wave packets.

Notice that if one of the two sources produces a wave packet with an additional phase factor, say $e^{i\phi}$, that phase factor will be present in both the terms in (11), and can be pulled out, becoming irrelevant.

The Hamiltonian governing the time evolution is that of two free particles. The two-particle eigenstate will simply be $|p, p'\rangle$ which means one particle has momentum $p$ and the other $p'$. One can thus write

$$H|p, p'\rangle = \left(\frac{p^2}{2m} + \frac{p'^2}{2m}\right)|p, p'\rangle \quad (12)$$

After traveling for a time $t$, the particles reach the screen. Time evolution of the initial state $|\phi_A, \phi_B\rangle$ can be worked out by introducing a complete set of two-particle momentum eigenstates:

$$|\psi(t)\rangle = e^{-iHt/\hbar}|\phi_A, \phi_B\rangle = e^{-iHt/\hbar} \sum_{p, p'}|p, p'|\langle p, p'\rangle|\phi_A, \phi_B\rangle$$

$$= \sum_{p, p'} e^{-\frac{i(p-p')^2 \Delta^2}{2\hbar}}|p, p'\rangle$$

$$= \sum_{p, p'}|p, p'\rangle \left[ \langle p|\phi_A\rangle\langle p'|\phi_B\rangle + \eta\langle p|\phi_B\rangle\langle p'|\phi_A\rangle \right]$$

$$= \sum_{p, p'}|p, p'\rangle\left[ \langle p|\phi_A(t)\rangle\langle p'|\phi_B(t)\rangle + \eta\langle p|\phi_B(t)\rangle\langle p'|\phi_A(t)\rangle \right]$$

$$= |\phi_A(t), \phi_B(t)\rangle, \quad (13)$$

where

$$\langle p|\phi_A(t)\rangle = e^{-\frac{ip^2t}{\hbar}}\langle p|\phi_A\rangle, \quad \langle p'|\phi_B(t)\rangle = e^{-\frac{ip'^2t}{\hbar}}\langle p|\phi_B\rangle. \quad (14)$$

From the momentum representation of $|\phi_A\rangle$ and $|\phi_B\rangle$, the position representation can be evaluated. The amplitude of finding the particles at positions $x_1$ and $x_2$ then works out to be

$$\psi(x_1, x_2, t) = \alpha \left( \frac{e^{-i(x_1-x_0)^2/\Delta^2}}{\sqrt{\pi\Delta^2}} + \frac{e^{-i(x_2+x_0)^2/\Delta^2}}{\sqrt{\pi\Delta^2}} + \frac{e^{-i(x_1+x_0)^2/\Delta^2}}{\sqrt{\pi\Delta^2}} - \frac{e^{-i(x_2-x_0)^2/\Delta^2}}{\sqrt{\pi\Delta^2}} \right), \quad (15)$$

where $\Delta \equiv 2\hbar/m$, and $\alpha = \frac{1}{\sqrt{2\pi e^{2i\lambda/\pi}}}$. For simplicity we introduce the notation $\psi(x_1, x_2, t) = \psi(x_1, x_2, t)$. Joint probability density of finding the particles at $x_1$ and $x_2$ is given by

$$|\psi(t)|^2 = \frac{1}{\pi \sigma^2} \left( e^{-\frac{2e^2(x_1-x_2)x_0}{e^4 + \Delta^2}} + e^{\frac{4e^2(x_1-x_2)x_0}{e^4 + \Delta^2}} + 2 \sigma e^{\frac{4e^2(x_1-x_2)x_0}{e^4 + \Delta^2}} \cos\left( \frac{4e^2(x_1-x_2)x_0}{e^4 + \Delta^2} \right) \right), \quad (16)$$

where $\sigma^2 = e^2 + \Delta^2/2$. The above simplifies to

$$|\psi(t)|^2 = \frac{2}{\pi \sigma^2} e^{-\frac{2\Delta^2}{e^4 + \Delta^2}} \left( \frac{e^{\frac{4\Delta^2(x_1-x_2)x_0}{e^4 + \Delta^2}}}{\sin\left( \frac{4\Delta^2(x_1-x_2)x_0}{e^4 + \Delta^2} \right)} \right) \cos\left( \frac{4\Delta^2(x_1-x_2)x_0}{e^4 + \Delta^2} \right) \quad (17)$$

The RHS of Eqn. (17) represents an interference pattern in the joint probability of detection of the two particles, with respect to the distance between the two positions $x_1$ and $x_2$ on the screen. For $\eta = 1$, it constitutes the HBT effect for massive particles, which obey Bose statistics. The same result will also apply to independent photons with the proviso that $\Delta = \lambda L/\pi$, where $\lambda$ is the wavelength of the photons and $L$ is the distance traveled by them in time $t$. In fact, the relation $\Delta = \lambda L/\pi$ may also be used for massive particles in which case $\lambda$ will represent the d’Broglie wavelength of a particle. It is easy to check that, for $|x_1 - x_2|, x_0 \ll r_{A1} + r_{A2}, r_{B1} + r_{B2}$, the cosine term in (5) reduces to $\cos(4x_0(x_1 - x_2)/\Delta)$, which is the same as the cosine term in (17), provided that $e^4 \ll \Delta^2$.

At this stage it may be useful to understand the physical meaning of various terms in the joint probability distribution (16). In our usual classical way of thinking, we imagine that there is a possibility of the particle from source A reaching $x_1$ and that from source B reaching $x_2$. The solid lines in Fig. 1 represents this possibility and the first term in (16) represents its probability. There also exists a possibility of the particle from source A reaching $x_2$ and that from source B reaching $x_1$. The dashed lines in Fig. 1 represent this possibility and the second term in (16) represents its probability. If two independent particles can interfere with each other, there is also exists possibility of particles from A and B partially contributing to the particles detected at $x_1$, and at $x_2$. Since the particles are identical, we have no way of knowing which source they came from. In Fig. 1, the solid orange line and the dotted blue line represent the probability of A and B contributing to the particle reaching $x_1$, and the solid blue line and the dotted orange line represent the probability of A and B contributing to the particle reaching $x_2$. The last two terms in (16) represent this possibility. One can see that if the particles are not
identical, the last two terms would not be there. This argument is in agreement with the fact that the HBT effect cannot be seen for particles which are not identical.

The effect of the last two terms can also be interpreted as the interference between the processes represented by the solid and the dashed lines. For certain values of \( x_1, x_2 \) it might so happen that the solid lines process and the dashed lines process destructively interfere. In that case, there will be no simultaneous detection of particles at all.

The visibility of this interference pattern is

\[
 \frac{1}{\cosh \left( \frac{x^2_{1} + x^2_{2}}{2 \sigma^2} \right)},
\]

which is bounded from above by 1. Contrast this with the classical HBT effect described by (5), where the visibility cannot be greater than 1/2. This implies that there are certain distances between the detectors 1 and 2 for which the probability of detecting particles simultaneously is zero! The probability of detecting two particles very close to each other is enhanced. This can be interpreted as a bunching effect. Remarkably, the particles tend to get bunched together even when there is no interaction between them. This is a purely quantum mechanical effect and has been experimentally observed in photons [6] as well as massive particles [7–9].

For \( \eta = -1 \), the relation (17) implies that the probability of simultaneously detecting two particles very close to each other is nearly zero! Even when the particles strike the screen at random, there is a certain probability of two of them hitting the screen very close to each other. In the case \( \eta = -1 \), the probability of landing very close to each other is even smaller than this random chance. It appears as if the particles are repelling each other. This is what is called anti-bunching effect and has been observed for particles following Fermi-Dirac statistics, e.g., electrons [10].

IV. ENTANGLED PARTICLES

Let us now investigate the scenario where the particles are entangled. There are certain sources of photons which generate photons in entangled pairs. Entanglement manifests itself in strong quantum correlations between the two particles. To our knowledge, the effect of entanglement on the HBT effect has not been quantified. Einstein, Podolsky and Rosen (EPR) first drew attention to a momentum entangled state of two particles [31]

\[
 \Psi_{EPR}(x_1, x_2) = \int_{-\infty}^{\infty} dp e^{i p x_1} \frac{1}{\sqrt{\pi}} e^{-\frac{p^2}{\sigma^2}} e^{-i 2 \sigma^2 \frac{x_1 x_2}{\sigma^2}} ,
\]

which can be written in Dirac notation as

\[
 |\Psi_{EPR}\rangle = \int_{-\infty}^{\infty} |p\rangle_1 |p\rangle_2 e^{-i 2 \sigma^2 \frac{x_1 x_2}{\sigma^2}} dp,
\]

where labels 1 and 2 refer to particle 1 and 2, respectively. This state is for distinguishable particles. If one were to write an EPR state for identical particles, in our label-free approach, it would be the following

\[
|\Psi_{EPR}^{ident}\rangle = \int_{-\infty}^{\infty} |p, -p\rangle e^{-i 2 \sigma^2 \frac{x_1 x_2}{\sigma^2}} dp .
\]

The amplitude of finding the particles at \( x_1 \) and \( x_2 \) is given by

\[
\langle x_1, x_2 |\Psi_{EPR}^{ident}\rangle = \int_{-\infty}^{\infty} \left[ \langle x_1 |p\rangle \langle x_2 | -p\rangle + \eta \langle x_1 | -p\rangle \langle x_2 |p\rangle \right] e^{-i 2 \sigma^2 \frac{x_1 x_2}{\sigma^2}} dp,
\]

which will be just the symmetrized or antisymmetrized form of (18).

The problem with the EPR state (18) is that it cannot be normalized, and also it does not describe particles with varying degree of entanglement. To address these shortcomings, we introduce a generalized EPR state for identical particles

\[
|\Psi\rangle = C \int_{-\infty}^{\infty} dp \int_{-\infty}^{\infty} dq |q + p, q - p\rangle e^{-i 2 \sigma^2 \frac{x_1 x_2}{\sigma^2}} e^{-\frac{q^2}{\Omega^2}} e^{-\frac{p^2}{\sigma^2}} ,
\]

where \( q + p \) and \( q - p \) label single-particle momentum eigenstates, \( C \) is a normalization constant, and \( \sigma, \Omega \) are certain parameters. In the limit \( \sigma, \Omega \to \infty \) the state (22) reduces to the EPR state (20), if \( -2x_0 \) here is identified with \( x_0 \) in the EPR state.

The two-particle amplitude of finding them at \( x_1 \) and \( x_2 \) is given by

\[
\Psi(x_1, x_2) = \sqrt{\frac{\sigma}{\pi \Omega}} \left( e^{-(x_1 - x_2 - 2x_0)^2/\sigma^2} e^{-(x_1 + x_2)^2/4\Omega^2}
\]

\[
+ \eta e^{-(x_1 - x_2 + 2x_0)^2/\sigma^2} e^{-(x_1 + x_2)^2/4\Omega^2} \right) .
\]

The state (23) is an extended version of the generalized EPR state introduced earlier [32]. It is straightforward to show that \( \Omega \) and \( \sigma \) quantify the position and momentum spread of the particles in the \( x \)-direction. The interesting thing about this state is that for \( 2\Omega = 1/\sigma = e \sqrt{2} \), it is no longer entangled and reduces exactly to the symmetric state (11) studied in the last section, which is a symmetrized or anti-symmetrized product of two Gaussians centered at \( x_0 \) and \( -x_0 \). So the entangled state is essentially two shifted Gaussians entangled with each other. The state (23) is symmetric under the interchange of the two particles, thus describing bosonic particles.

The stage is now set to study HBT effect with two entangled particles, described by the state (23). The two particles travel in the \( y \)-direction for a time \( t \) before reaching the screen. During this time, the states evolves in transverse \( x \)-direction too. As done in the last section, we ignore the time evolution in the \( y \)-direction, and only consider the evolution in the \( x \)-direction. If one is dealing with photons, one can use an alternative wave-packet
evolution [33]. The state of the two particles, on reaching the screen (or detectors), is given by

\[
\Psi(x_1, x_2, t) = C_t e^{i \frac{(x_1 + x_2)^2}{4 \sigma^2 + i \delta}} \left( \exp \left[ -\frac{(x_1 - x_2 - 2x_0)^2}{1/\sigma^2 + i \delta} \right] + \eta \exp \left[ -\frac{(x_1 - x_2 + 2x_0)^2}{1/\sigma^2 + i \delta} \right] \right),
\]

where \( C_t = \sqrt{\frac{\Omega^2 + \left( \frac{\delta}{\sigma^2} \right)^2}{\frac{1}{\sigma^2} + \left( \frac{\delta}{\sigma^2} \right)^2}} \left( \frac{1}{\sigma^2} + \left( \frac{\delta}{\sigma^2} \right)^2 \right)^{-1/4}, \delta = 4\hbar/m = 2\lambda L/\pi \) and \( L \) is the distance in the y-direction, traveled by the particles during time \( t \).

The probability density of joint detection of particles at \( x_1 \) and \( x_2 \) can now be calculated, and is given by

\[
|\Psi(x_1, x_2, t)|^2 = |C_t|^2 e^{-\frac{8(x_1-x_2)^2}{\sigma^2}} e^{-\frac{2(x_1-x_2)^2+2x_0^2}{\sigma^2}} \cosh \left( \frac{8(x_1-x_2)x_0/\sigma^2}{1/\sigma^4 + \delta^2} \right) \left( 1 + \eta \frac{\cosh \left( \frac{8(x_1-x_2)x_0/\sigma^2}{1/\sigma^4 + \delta^2} \right)}{\cosh \left( \frac{8(x_1-x_2)x_0/\sigma^2}{1/\sigma^4 + \delta^2} \right)} \right).
\]

The above expression closely resembles (17) derived for particles which are not entangled. Let us explore it in the situation when the entanglement between the two particles is strong. Entanglement is strong when \( \sigma \) is large and one can safely assume \( 1/\sigma^4 \ll \delta^2 \). In this limit, the cosine term becomes \( \cos[8(x_1-x_2)x_0/\delta] = \cos[4(x_1-x_2)x_0/\Delta] \), which means that the interference fringe width is the same as in the case of independent particles and also in the classical case. The Gaussian terms in (25) assume the approximate form \( e^{-\frac{2(x_1-x_2)^2}{\sigma^2}} e^{-\frac{2(x_1-x_2)^2+2x_0^2}{\sigma^2}} \). These Gaussians represent broad profiles both in \( x_1 + x_2 \) and \( x_1 - x_2 \). Therefore it appears that entanglement does not cause any suppression of HBT effect, and remains almost as if it is for independent particles.

In the opposite limit, i.e., when the entanglement goes to zero, one can write \( 4\sigma^2 = 1/\sigma^2 \equiv 2e^2 \) (say). In this limit, (25) exactly reduces to (17), as expected.

\[ 5 \]

V. THE GHOSH-MANDEL EXPERIMENT

In the light of the preceding analysis, we now take a fresh look at an old quantum optics experiment by Ghosh and Mandel [34]. This experiment was among the category of first experiments showing spatial correlation of photons. A UV laser beam was incident on a non-linear crystal resulting in the production of a pair of downconverted photons. Such photons are known to be entangled, and show quantum correlations. The two photons travel in different directions at a small angle with respect to each other. Two mirrors are used to bring the two photons together, and two detectors, in the detection plane, detect them in coincidence (see FIG. 2). While a single detector saw no interference, a coincident count of the two detectors, as a function of their relative separation showed an interference pattern. The visibility of interference was greater than 1/2, which demonstrated the non-classical nature of photons. This experiment has also been discussed in a textbook [35], and the interference pattern is believed to be a result of non-local quantum correlation between the two photons [34, 35].

One would notice the close similarity between the Ghosh-Mandel experiment and our model system studying HBT effect with entangled particles. The two detectors in the Ghosh-Mandel experiment, at \( x_1 \) and \( x_2 \), see the photons reaching them after getting deflected from the two mirrors. In effect they see the photons as coming from two spatially separated virtual sources A and B (see FIG. 2). With this recognition, the setup in FIG. 2 is virtually the same as that in FIG. 1, and our model system captures the essence of the Ghosh-Mandel experiment. Our analysis shows interference of entangled particles and the visibility is close to 1.

However, the surprising part is that the same result is obtained when we use independent bosonic particles which are not entangled, as shown in section III. When independent bosonic particles are used, one sees an interference in the coincidence count as a function of the relative position of the detectors, and the visibility is close to 1. But that is the result that is obtained in the Ghosh-Mandel experiment too. This implies that in the Ghosh-Mandel experiment, if the photons pairs were not entangled, the result would be the same as that for entangled photons. Thus the effect seen in the Ghosh-Mandel experiment is essentially the HBT effect. As the interference in the HBT effect is independent of whether the two particles are entangled or not, the Ghosh-Mandel experiment is not a demonstration of non-local quantum correlation between photons, as many seem to believe. However, it may be the first unambiguous demonstration of interference between two photons, which is a completely non-classical effect in itself, and probably would not have been expected by Dirac [3].
VI. CONCLUSION

To summarize, we have used wave-packets to study the HBT effect in quantum particles following Bose-Einstein and Fermi-Dirac statistics, using a recently introduced label-free analysis of indistinguishable particles. The bunching and anti-bunching has been demonstrated through a simple analysis. We have also analyzed the HBT effect for pairs of particles which are entangled in position and momentum through an EPR like state. These entangled particles also show an HBT effect which is not different from the HBT effect in independent particles, in any noticeable way.

We have also argued that the Ghosh-Mandel experiment is essentially the HBT effect with entangled particles. However, the interference seen in that experiment, is not a consequence of any non-local correlation between the two photons. Exactly the same effect would be observed if the photons were not entangled.

ACKNOWLEDGMENTS

This work is inspired by the lucid exposition of the HBT effect by N.D. Hari Dass. Ushba thanks the Centre for Theoretical Physics for providing her the facility of the Centre during the course of this work.
