DEVELOPMENT OF CHLOROPLAST MICROSATELLITE MARKERS FOR THE ENDANGERED *MAIANTHEMUM BICOLOR* (ASPARAGACEAE S.L.)

HANA PARK, CHANGKYUN KIM, YOU-MI LEE, AND JOO-HWAN KIM

Department of Life Science, Gachon University, Seongnam, Gyeonggi 13120, Republic of Korea; and Korea National Arboretum, Pocheon, Gyeonggi 11186, Republic of Korea

**Premise of the study:** Ten polymorphic chloroplast microsatellite (cpSSR) markers were developed and characterized in an endemic and endangered herb, *Maianthemum bicolor* (Asparagaceae s.l.), for use in conservation genetics.

**Methods and Results:** Primer sets flanking each of the 10 cpSSR loci in noncoding regions of the chloroplast genome of *M. bicolor* were designed. These cpSSR markers were tested on a total of 33 adult individuals from three natural populations in South Korea. The number of alleles per locus ranged from two to three. The unbiased haplotype diversity per locus ranged from 0.061 to 0.682. All markers were successfully transferred to the congeneric species *M. japonicum*, *M. bifolium*, and *M. dilatatum* with polymorphisms among the species.

**Conclusions:** The developed cpSSR markers will be useful in assessing the genetic diversity and population structure of *M. bicolor* and will help to infer its molecular identification, thereby providing a basis for conservation.

**Key words:** Asparagaceae s.l.; conservation; endangered species; genetic diversity; *Maianthemum bicolor*; microsatellite.

*Maianthemum bicolor* (Nakai) Cubey (Asparagaceae s.l.) is an endemic perennial herb of South Korea (Oh, 2007). This species is characterized by dioecious flowers and tepal color that is green at the early stage of the flowering period and changes to dark purple as it grows (Yang, 2007). Therefore, it is visually possible to distinguish the species after the flower and fruit appear. Natural populations of *M. bicolor* are facing extinction due to habitat deterioration, low germination rates, and overexploitation by humans due to the species’ ornamental value (Chang et al., 2005; Lee et al., 2007). In addition, all local populations of *M. bicolor* growing on the ridges of mountains at altitudes higher than 1300 m above sea level are highly fragmented, and those habitats are isolated with discontinuous distribution (Lee et al., 2007; Oh, 2007). Both in situ and ex situ conservation programs are being undertaken to secure the wild populations (Lee et al., 2007), but neither the extent of genetic diversity nor the population structure of *M. bicolor* has been clearly analyzed. Thus, there is an urgent need for development of useful molecular markers for conservation genetics.

Although nuclear markers are excellent for use in most population genetic analyses (Ding et al., 2008; Kim et al., 2008; Tang et al., 2008; Guichoux et al., 2011), they are not suitable for phylogeographic and phylogeographic studies above species level due to high substitution rates (Powell et al., 1996). Chloroplast simple sequence repeat (cpSSR) markers are mainly distributed throughout noncoding regions, which show higher sequence variation than coding regions (Powell et al., 1995). Moreover, the cpSSR markers developed from a species are frequently applicable to amplify homologous regions across related taxa (Diekmann et al., 2012). Therefore, cpSSR markers can be applied for conservation genetics of endangered plant species and can be used to determine molecular identification and genetic relationships among closely related species (Clark et al., 2000; Huang et al., 2015) as complementary tools of nuclear markers.

Here, we provide 10 cpSSR markers for *M. bicolor* to facilitate conservation and molecular identification. These markers were developed from the complete chloroplast genome sequences of *M. bicolor* and tested on three natural populations. We also examined the transferability of the markers to three congeneric species, *M. japonicum* (A. Gray) LaFrankie, *M. bifolium* (L.) F. W. Schmidt, and *M. dilatatum* (Alph. Wood) A. Nelson & J. F. Macbr.; the former is closely related to *M. bicolor* and the latter two are more distantly related within the genus (Kim and Kim, unpublished).

**METHODS AND RESULTS**

To determine the complete chloroplast genome sequences of *M. bicolor*, we sampled fresh leaf material from Mt. Deogyu, South Korea. Genomic DNA was extracted using a DNeasy Plant Mini Kit (QIAGEN, Valencia, California, USA). The chloroplast genome of *M. bicolor* was sequenced using a genome skimming approach on an Illumina MiSeq sequencer (Illumina, San Diego, California, USA) and assembled with Geneious version 7.13 (Biomatters, Auckland, New Zealand). The chloroplast genome of *M. bicolor* is 157,176 bp in length. It displays a typical quadripartite structure, with the large single-copy region (55,698 bp, 54.5% of the total genome) separated from the small single-copy region (18,394 bp, 11.7%) by two inverted repeat regions (26,542 bp, 16.9% each). The GC content is 37.6% (Park et al., unpublished).

The cpSSR regions of *M. bicolor* were searched through the complete chloroplast genome sequence using a tandem repeat search tool in Geneious with the parameters set to ≥2 mononucleotide repeats, ≥4 di- and trinucleotide repeats, and ≥3 tetra-, penta-, and hexanucleotide repeats. A total of 109 repeat motifs were identified in the chloroplast genome, among which the most frequent types...
were mononucleotide (124 [73.4%]) and dinucleotide (32 [18.9%]), while tri- (3 [1.8%]), tetra- (8 [4.7%]), and pentanucleotides (2 [1.2%]) were rare. Forty-one loci were randomly selected for screening. We designed 41 primer pairs using Primer3 (Rozen and Skaletsky, 1999) under the following criteria: (1) guanine-cytosine content 30–70%, (2) annealing temperature (°C) 55–65, (3) primer size 18–25 bp in length, and (4) amplicon size 150–500 bp in length. To check the amplification success and variability, two individuals from each of three populations of *M. bicolor* (Mt. Deogyu, Mt. Seorak, and Mt. Daeam; Appendix 1) were selected (Appendix 2).

PCR amplification was carried out in a total volume of 25 μL containing 2.5 μL of 10× PCR buffer (10 mM Tris-HCl [pH 8.3], 1.5 mM MgCl₂, and 50 mM KCl), 0.25 mM of each dNTP, 5 μL of each 6-FAM fluorescently labeled forward and unlabeled reverse primer, 1 unit of Taq DNA polymerase, and 100 ng of DNA template. Amplification of genomic DNA was performed on a Veriti thermal cycler (Applied Biosystems, Carlsbad, California, USA). Fragment length polymorphism was detected on an ABI 3730 DNA Analyzer with GeneScan 500 ROX Size Standard (Applied Biosystems). Peak data were analyzed using Peak Scanner version 1.0 (Applied Biosystems). The authenticity of the loci amplified in *M. bicolor* populations was confirmed by sequencing the representative PCR products on an ABI 3730 automated sequencer (Applied Biosystems) using the amplification primers. Consensus DNA sequences were assembled for each individual using DNA Baser version 3 (Heracle BioSoft SARL, Pitești, Romania). Of the 41 primer pairs screened, 10 primer sets showed length variation in cpSSR regions and were developed further (Table 1); 31 were monomorphic and not developed any further (Appendix 2).

Thirty-three adult individuals from three natural populations of *M. bicolor* were used to characterize 10 polymorphic cpSSR loci (Table 2). All polymorphic loci are located in the noncoding regions in which the mutations are usually neutral (Table 1). Polymorphism parameters were calculated with POPGENE version 1.31 (Yeh et al., 1997). The allelic variation (A) in 10 cpSSR loci ranged from 29.9 to 43.5 (Table 2).

### Table 1. Characteristics of 10 polymorphic chloroplast microsatellite markers developed for *Maianthemum bicolor*.

| Mean  | 2.1 | 0.409 |              |    |              |    |
| Total | 21 | 0.775 |              |    |              |    |

Note: *A* = number of alleles; *H* = unbiased haplotype diversity; *n* = number of individuals.

*a Asterisk denotes specific alleles occurred in one or more individuals of each population.

http://www.bioone.org/loi/apps

2 of 5
from two to three, while the unbiased haplotype diversity ($H$) ranged from 0.061 to 0.682, with an average value of 0.409 (Table 2). Ten cpSSR markers amplified a total 21 alleles. Of these, 10 alleles specifically occurred in one or more individuals of each population; four were specific for the Mt. Deogyu population, three for the Mt. Seorak population, and three for the Mt. Daeam population (Table 2). All polymorphic primers developed for *M. bicolor* were able to successfully amplify cpSSR regions in three congeneric species (*M. japonicum*, *M. dilatatum*, and *M. bilobatum*) sampled from two populations in South Korea and showed polymorphisms among the species (Appendix 3).

### CONCLUSIONS

The cpSSR markers developed here are useful for formulating an in situ conservation strategy of the endangered *M. bicolor* populations by estimating the level of genetic diversity and population structure. The cpSSR markers will also be useful to determine the minimum size of the ex situ core collection that captures the genetic diversity of wild populations of *M. bicolor*. All of the cpSSR markers designed here for amplification of *M. bicolor* are applicable to other congeneric species and are a means for species verification in combination with morphological identification.
