(Dated: November 24, 2009)

We report a novel superconducting (SC) and antiferromagnetic (AF) hybrid state in SrFe$_2$As$_2$ revealed by $^{75}$As nuclear magnetic resonance (NMR) experiments on a single crystal under hydrostatic pressure up to 7 GPa. The NMR spectra at 5.4 GPa indicate simultaneous development of the SC and AF orders below 30 K. The nuclear spin-lattice relaxation rate in the SC domains shows a substantial residual density of states, suggesting proximity effects due to spontaneous formation of a nano-scale SC/AF hybrid structure. This entangled behavior is a remarkable example of a self-organized heterogeneous structure in a clean system.

Keywords: iron pnictide, superconductivity, SrFe$_2$As$_2$, high pressure, NMR

Competition between magnetism and superconductivity is ubiquitous in unconventional superconductors such as cuprates and heavy fermions,$^{1,2}$ as is the case for iron pnictides$^{1,2}$. Precise determination of the phase diagram, in particular whether the antiferromagnetic (AF) and the superconducting (SC) phases mutually exclude or coexist, is often hampered by compositional and structural inhomogeneity, which are inevitable when the SC state is induced by carrier doping.$^{3,4}$

While this is the case for cuprates, there is another route to the SC state in iron pnictides. SrFe$_2$As$_2$ shows a phase transition from the tetragonal paramagnetic (PM) state into the orthorhombic AF state below 200 K at ambient pressure.$^{5,6}$ It is reported to become SC not only by chemical substitution$^{7,8}$ to change carrier concentration but also by applying sufficiently high pressure to suppress the AF state.$^{9,10,11}$ The pressure-induced SC state provides an opportunity to unravel intrinsic behavior caused by interplay between the AF and SC order unaffected by disorder. This motivated us to perform high-pressure NMR spectroscopy, a powerful tool to examine coexistence of the SC and AF states.

We developed a new type of opposed-anvil pressure cell$^{12}$, which enables NMR experiments in quasi-hydrostatic pressure up to 9.4 GPa by using argon as the pressure transmitting medium$^{13}$. The cell was mounted on a geared double-axis goniometer allowing precise sample alignment within one degree. The single crystals of SrFe$_2$As$_2$ were prepared by self-flux method. A small piece ($1 \times 0.7 \times 0.15$ mm$^3$) was cut from the sample used in the study at ambient pressure$^{6}$. NMR signals from Sn and Pt foil were used to determine pressures in situ$^{12}$.

Figure 1 shows the $^{75}$As-NMR spectra in the PM and AF states at various $P$. The quadrupole interaction splits the resonance of $^{75}$As nuclei with spin I = 3/2 into three lines corresponding to the transitions $I_z = m \rightarrow m - 1$ ($m = \pm 1/2, 3/2$) at the frequencies $f_{\text{res}} = \gamma |H + H_{\text{hf}}| + (m - 1/2)\nu + (\text{second-order quadrupole shift})$, where $\gamma = 7.2902$ MHz/T is the gyromagnetic ratio, $H_{\text{hf}}$ is the hyperfine field from the Fe spins, and $\nu$ is proportional to the electric field gradient along the field direction. In the PM state, $H_{\text{hf}}$ is uniquely given and proportional to the external field, $H_{\text{hf}} = K^\alpha H$, where $K^\alpha$ is the Knight shift along the $\alpha$ direction. In the AF state the spectra for $H \parallel c$ split symmetrically into two sets of three lines. However, the central line ($m = 1/2$) for $H \perp c$ does not split, indicating that the hyperfine fields are parallel to the $c$-axis, $H_{\text{hf}} = (0, 0, \pm \Delta)$. This is compatible with the commensurate stripe AF structure with $q = [101]$ and the AF moments parallel to the $a$-axis as previously reported$^{6}$. Our results prove that the ground state below 4.2 GPa has the stripe-type AF order with the orthorhombic structure.

The AF transition temperature $T_N$ can be determined from the vanishing of the PM spectral intensity [Fig. 2(a)]. The hysteresis provides clear evidence for a first-order transition. Below 4.2 GPa, no fraction of the PM state remains at low $T$. Figure 2(b) shows $T$-dependence of the nuclear spin-lattice relaxation rate $T_1^{-1}$ divided by $T$. $(T_1T)^{-1}$ shows an upturn as $T$ approaches $T_N$ below 4.2 GPa, indicating development of AF spin fluctuations in the PM state even though the transition is first-order. At 5.4 GPa, an increase of $(T_1T)^{-1}$ is also observed above 30 K, followed by a sudden decrease at lower $T$. As we discuss later, the PM spectrum does not vanish at low $T$ at 5.4 GPa and there is sufficient evidence for a bulk SC state. The reduction of $(T_1T)^{-1}$ is then a consequence of opening of the energy gap in the SC state. When $P$ is increased to 7.2 GPa, $(T_1T)^{-1}$ is nearly independent of $T$, exhibiting neither an SC transition nor development of AF fluctuations.

Let us examine the microscopic features of the SC state at 5.4 GPa. Figure 3 shows the NMR spectra obtained by sweeping frequency at fixed fields$^{23}$. The spectra im-
mediately above the SC transition temperature $T_c$ show identical features to those at 35 K [Fig. 3(a)], and hence belong to the PM and normal (N) state. The central line for $H \parallel c$ broadens suddenly below $T_c$ [see the insets and Fig. 3(b)] due to field distribution in the SC mixed state. At 4.2 K, the spectra clearly show coexistence of the tetragonal PM-SC and the orthorhombic AF domains with comparable volume fractions as indicated in Figs. 3(a) and (c). The broad asymmetric central line for $H \perp c$ at 26 K [Fig. 3(c)] indicates that the AF domains appear immediately below $T_c$. Thus only one phase transition from the N-PM state to the SC/AF coexisting state occurs over the entire sample. This would not be possible if the coexistence were due to inhomogeneity. Instead, the results strongly suggest formation of a self-organized SC/AF hybrid structure.

The $T$-dependence of $(T_1T)^{-1}$ and the Knight shifts were measured at 5.4 GPa [Figs. 4(a) and (b)]. Both exhibit sudden decrease due to opening of the SC gap with spin-singlet pairing below $T_c = 27 - 30$ K, depending slightly on the field values. The values of $T_c$ agree well with the onset of the diamagnetic response [Fig. 4(c)]. These results provide definitive evidence for the bulk SC state. What is anomalous though is that $(T_1T)^{-1}$ approaches a finite value towards 0 K, indicating a finite density of state (DOS), i.e., gapless superconductivity. Moreover, the SC and AF domains show nearly the same value of $(T_1T)^{-1}$ at low $T$. To demonstrate good electronic homogeneity, the recovery curves in the relaxation measurements are shown in Figs. 4(d)–(f) at several $T$. All curves are fit extremely well by assuming a single value of $T_c$. The inset shows the $P$-$T$ phase diagram. $T_N$ is determined from the 50% recovery of the PM intensity on warming in (a) (open diamonds). The bulk SC transition (open squares) is detected in our NMR experiment only at 5.4 GPa. $T_c$ is determined from the peak in $(T_1T)^{-1}$ at 11 T for $H \perp c$. The SC transition is absent below 4.2 GPa and at 7.2 GPa. Crosses represent the data reported based on the resistivity (for AF) and the ac susceptibility (for SC) measurements.
FIG. 3: (Color) $^{75}$As-NMR spectra at 5.4 GPa showing the coexistence of the AF and SC states. The insets show the color plots indicating the $T$-dependence of the spectral intensity distribution near the central line. The white dashed lines indicate the $T$ values of the spectra in the main panels. (a) The NMR spectra for $H \parallel c$ at 11 T measured at 28 K (above $T_c$), 18 K (below $T_c$), and 4.2 K. At 4.2 K, the spectrum shows contributions both from the commensurate stripe-type AF domains (gray arrows) and from the PM-SC domains (red arrows). (b) The PM (SC or normal) central lines for $H \parallel c$ at 6.6 T. Anomalous line shape with asymmetric broad tail is observed for $18 K < T < T_c$ (see the inset). Standard models of vortex lattices are unable to fit the spectrum at 25 K even if an extremely short penetration depth $\lambda$ is assumed. An example is shown by the red line calculated with the modified London model for a rectangular vortex lattice\[15, 16, 17\]. (c) The spectra for $H \perp c$ at 11 T. At 4.2 K, the satellite lines from the AF domains split into two sets. The azimuth angle dependence of the satellite positions in the $ab$-plane are reproduced by the asymmetry parameter $|v_a - v_b|/v_c = 0.15$ as shown by the dashed lines. This proves the twinned orthorhombic structure of the AF domains. The broadened spectrum at 26 K from the AF domains indicates modulation of AF moments and the structure, most likely an incommensurate spin-density-wave type.

pairing, or (iii) proximity effect from nearby AF domains. We can exclude the case (i) based on the nearly field-independent and uniform behaviour of $(T_1 T)^{-1}$. Since the gapless behaviour persists down to 1.5 K, orders of magnitude smaller than $T_c$, the case (ii) alone is also unlikely. Nevertheless, proximity effects from the AF domains (case iii) can squeeze small gaps on parts of the Fermi surfaces. Note that the size of SC domains must be sufficiently small in order for proximity to be effective. This suggests spontaneous formation of nano-scale periodic structure of alternating SC and AF domains.

We now add the SC phase boundary to the $P$-$T$ phase diagram in the inset of Fig. 2(b). The SC/AF hybrid state appears only in a very narrow $P$-region over 5 GPa. It is reported that improved hydrostaticity results in higher critical pressure $P_c$ for the appearance of the SC state\[18\]. Our value $P_c \sim 5$ GPa is higher than the previous results, indicating good hydrostaticity of argon medium. The narrow $P$-range of the SC state is in marked contrast to the stable pure SC state obtained by chemical doping\[7, 8, 19, 20\], and points to a rather fragile nature of the SC/AF hybrid state. Note that the equal numbers of electrons and holes are preserved under pressure but not by doping.

Next, we focus on the $T$-dependence of the spectra at 5.4 GPa immediately below $T_c$. We first discuss the spec-
In the same $T$ region ($T^* < T < T_c$), we observed anomalous spectral shape as shown in Fig. 3(b). The central line at 25 K for $H \parallel c$ consists of a moderately broadened line on top of a much broader tail. While the former persists to low $T$, the latter disappears below $T^*$. Since similar values of $T_1^{-1}$ are obtained on and off the main peak, they both belong to the SC-PM domain. Note that $T_1^{-1}$ for the AF domain is smaller by a factor of three at 25 K [Fig. 4(a)]. The width of the broad tail decreases slightly with increasing field, indicating that the origin is related to the SC diamagnetic current. Nevertheless, the entire line shape cannot be explained by standard vortex lattices with any choice of parameters (see the red line). The puzzling line shape above $T^*$ indicates anomalous modulation of the SC diamagnetic current with a much shorter length scale than the penetration depth, where modulation of the AF moments also appears.

Coexistence of AF and SC states has been observed in some heavy fermion compounds. For example, CeRhIn$_5$ under pressure shows microscopic coexistence of the AF and SC orders, which are spatially indistinguishable [17, 21]. In CeIn$_3$ the AF and SC orders occur in different spatial region at different transition temperatures [17, 22]. The case of SrFe$_2$As$_2$ differs from any of examples known to date in that the SC and AF orders are spatially distinguished but occur simultaneously forming a spontaneous SC/AF hybrid structure.

FIG. 4: (Color online) Evidence for bulk SC state at 5.4 GPa. (a) The $T$-dependence of $(T_1T)^{-1}$ in the PM state for $H \perp c$ at 11 T (blue) and for $H \parallel c$ at 11 T (orange) and at 6.6 T (red). The blue and the red data are identical to those shown in Fig. 2(b). Opening of the SC gap causes sudden decrease of $(T_1T)^{-1}$ below $T_c$. Also shown are $(T_1T)^{-1}$ data in the AF state for $H \perp c$ at 11 T (sky blue). All measurements were made on the central line, whose positions are shown by the arrows in Fig. 3. (b) The $T$-dependence of the Knight shift for $H \parallel c$ at 6.6 T and 11 T. The reduction below $T_c$ indicates the spin-singlet pairing in the SC state. (c) The ac susceptibility measured by the self resonance method using the NMR coil. The change of the resonating frequency $-\Delta f$ represents the Meissner shielding. (d)-(f) Typical recovery curves of the nuclear magnetization during the $T_1$ measurement at 28 K (immediately above $T_c$), 22 K, and 4.2 K (below $T_c$) for $H \parallel c$ at 11 T. Each curve is fit very well to the formula for spin/2 nuclei, $(exp(-t/T_1)) + 9 exp(-6t/T_1))/10$, with a single value of $T_1$, supporting uniform relaxation process.
