Abstract
Smoking causes a variety of adverse effects on organs that have no direct contact with the smoke itself such as the liver. It induces three major adverse effects on the liver: direct or indirect toxic effects, immunological effects and oncogenic effects. Smoking yields chemical substances with cytotoxic potential which increase necroinflammation and fibrosis. In addition, smoking increases the production of pro-inflammatory cytokines (IL-1, IL-6 and TNF-α) that would be involved in liver cell injury. It contributes to the development of secondary polycythemia and in turn to increased red cell mass and turnover which might be a contributing factor to secondary iron overload disease promoting oxidative stress of hepatocytes. Increased red cell mass and turnover are associated with increased purine catabolism which promotes excessive production of uric acid. Smoking affects both cell-mediated and humoral immune responses by blocking lymphocyte proliferation and inducing apoptosis of lymphocytes. Smoking also increases serum and hepatic iron which induce oxidative stress and lipid peroxidation that lead to activation of stellate cells and development of fibrosis. Smoking yields chemicals with oncogenic potential that increase the risk of hepatocellular carcinoma (HCC) in patients with viral hepatitis and are independent of viral infection as well. Tobacco smoking has been associated with supression of p53 (tumour suppressor gene). In addition, smoking causes suppression of T-cell responses and is associated with decreased surveillance for tumour cells. Moreover, it has been reported that heavy smoking affects the sustained virological response to interferon (IFN) therapy in hepatitis C patients which can be improved by repeated phlebotomy. Smoker’s syndrome is a clinico-pathological condition where patients complain of episodes of facial flushing, warmth of the palms and soles of feet, throbbing headache, fullness in the head, dizziness, lethargy, prickling sensation, pruritus and arthralgia.

INTRODUCTION
Lighting a cigarette creates over 4000 harmful chemicals with hazardous adverse effects on almost every organ in the body. The impact of heavy smoking on the pathogenesis of liver disease and response to interferon therapy among chronic hepatitis patients has been overlooked. Before we begin this article; it is necessary to define who is a heavy smoker and to shed light on the common toxic constituents of cigarette smoking.

WHO IS A HEAVY SMOKER?
Heavy smokers are variably defined, some studies suggest exposure to two or more packets (≥40 cigarettes) a day for 10 years or more[1]. On the other hand, Marrero et al[2] have defined heavy smokers as those exposed to greater than 20 pack-years.

COMMON CONSTITUENTS OF CIGARETTE SMOKE
The constituents of smoke are contained in either the particulate phase or gas phase.

Particulate phase
Particulate phase components include tar, polynuclear hydrocarbons, phynol, cresol, catechol and trace elements (carcinogens), nicotine (ganglion stimulator and depressor), indole, carbazole (tumor accelerators)[3], and 4-aminobiphenyl[4].

Gas phase
Gas phase contains carbon monoxide (impairs oxygen transport and utilization), hydrocyanic acid, acetaldehyde, acrolein, ammonia, formaldehyde and oxides of nitrogen
Smoking yields chemical substances which induce hyperplasia of the bone marrow. The latter hypoxia. Hypoxia stimulates erythropoietin production capacity of red blood cells (RBCs) leading to tissue carboxyhaemoglobin and decreased oxygen carrying 

**ADVERSE EFFECTS OF SMOKING ON THE BODY**

Smokers are at greater risk for cardiovascular diseases (ischaemic heart disease, hypertension), respiratory disorders (bronchitis, emphysema, chronic obstructive lung disease, asthma), cancer (lung, pancreas, breast, liver, bladder, oral, larynx, oesophagus, stomach and kidney), peptic ulcers and gastroesophageal reflux disease (GERD), male impotence and infertility, blindness, hearing loss, bone matrix loss, and hepatotoxicity[8].

**ADVERSE EFFECTS OF SMOKING ON THE LIVER**

Beside the hazardous effects mentioned before; smoking causes a variety of adverse effects on organs that have no direct contact with the smoke itself such as liver. The liver is an important organ that has many tasks. Among other things, the liver is responsible for processing drugs, alcohol and other toxins to remove them from the body. Heavy smoking yields toxins which induce necroinflammation and increase the severity of hepatic lesions (fibrosis and activity scores) when associated with hepatitis C virus (HCV)[9] or hepatitis B virus (HBV) infection[10]. Cigarette smoking increases the risk of developing HCC among chronic liver disease (CLD) patients[11] independently of liver status. Association of smoking with hepatocellular carcinoma (HCC) irrespective of HBV status has been reported[12].

*How does smoking affect the liver?*

Smoking induces three major adverse effects on the liver: toxic effects either direct or indirect, immunological effects and oncogenic effects.

**Toxic effects of smoking on the liver**

**Direct toxic effect:** Smoking yields chemical substances with cytotoxic potentials[12]. These chemicals created by smoking induce oxidative stress associated with lipid peroxidation[13,14] which leads to activation of stellate cells and development of fibrosis. In addition, smoking increases the production of pro-inflammatory cytokines (IL-1, IL-6 and TNF-α) involved in liver cell injury[15]. It has been reported that smoking increases fibrosis score and histological activity index in chronic hepatitis C (CHC) patients[16] and contributes to progression of HBV-related cirrhosis[17].

**Indirect toxic effects (concomitant polycythemia)**

Heavy smoking is associated with increased carboxyhaemoglobin and decreased oxygen carrying capacity of red blood cells (RBCs) leading to tissue hypoxia. Hypoxia stimulates erythropoietin production which induces hyperplasia of the bone marrow. The latter contributes to the development of secondary polycythemia and in turn to increased red cell mass and turnover. This increases catabolic iron derived from both senescent red blood cells and iron derived from increased destruction of red cells associated with polycythemia[18,19]. Furthermore, erythropoietin stimulates absorption of iron from the intestine. Both excess catabolic iron and increased iron absorption ultimately lead to its accumulation in macrophages and subsequently in hepatocytes over time, promoting oxidative stress of hepatocytes[20]. Accordingly, smoking might be a contributing factor to secondary iron overload disease in addition to other factors such as transfusional haemodisordesis, alcoholic cirrhosis, thalassemia, sideroelastic anemia and porphyria cutanea tarda.

In the meantime, increased red cell mass and turnover are associated with increased purine catabolism which promotes excessive production of uric acid. Eventually uric acid is deposited in tissues and joints as manifested clinically by pricking sensation, pruritus and arthralgia[21] (Figure 1).

**Smoker’s syndrome:** Smoker’s syndrome is a clinicopathological condition reported in patients smoking ≥40 cigarettes or 10 stones of popular shisha (water-pipe) in Egypt per day, over a long time. These patients suffer from episodes of facial flushing, warmth of the palms and soles, throbbing headache, fullness in the head, dizziness, lethargy, pricking sensation, pruritus and arthralgia[22]. However, the majority of patients who smoke less than the described level are subject to biochemical changes rather than clinical manifestations.

Facial flushing, the most prominent symptom, is explained by capillary vasodilatation associated with increased blood flow through the skin. The vasodilatation may be attributed to the direct action of vasodilator constituents of the smoke as well as to excess haemoglobin saturation[23] reported among heavy smokers[24].

On examination of these smokers, the face appears dusky-red and/or pigmented, the pulse is full. The smokers suffer from hypertension, joint stiffness and swelling.
Some of them have experienced cerebrovascular and cardiovascular strokes. Laboratory studies have revealed an increased Hb level (> 160 g/L) and haematocrit (> 55 mL/100 mL) in almost all the patients and raised ALT (> 2 fold), uric acid (> 6 mg/dL), serum iron (> 165 μg/dL) and ferritin in most of the patients. Histopathological examination reveals hepatic necro-inflammation, apoptotic necrosis, fibrosis, and deposition of iron in hepatocytes as demonstrated by Perl’s stain.

IMMUNOLOGICAL EFFECTS OF SMOKING

Smoking affects both cell-mediated and humoral immune responses [25]. Nicotine blocks lymphocyte proliferation and differentiation including suppression of antibody-forming cells [15,23,24] by inhibiting antigen-mediated signaling in T-cells [25] and ribonucleotide reductase [25]. Furthermore, smoking induces apoptosis of lymphocytes [26] by enhancing expression of Fas (CD95) death receptor which allows them to be killed by other cells expressing a surface protein called Fas ligand (FasL). Smoking induces elevation of CD8+ T-lymphocytes [14], decreased CD4+ cells, impaired NK cell activity [27] and increases the production of pro-inflammatory cytokines (IL-1, IL-6, TNF-α) [15].

Although smoking has long-term adverse effects; cessation of smoking reversed these effects, such as elevation of NK activity which is detectable within one month of smoking cessation [28], elevation of both antibody- and cell-mediated immune responses as well as decreased proinflammatory cytokines and increased antioxidant activity.

ONCOGENIC EFFECTS OF SMOKING

Smoking yields chemicals with oncogenic potentials such as hydrocarbons, nitrosamine, tar and vinyl chloride [29]. Cigarette smoking is a major source of 4-aminobiphenyl, a hepatic carcinogen which has been implicated as a causal risk factor for HCC [9]. Smoking increases the risk of HCC in patients with viral hepatitis [9,30,31]. Furthermore, recent data from China and Taiwan have shown an association of smoking with liver cancer independent of HBV status [10,11]. Tobacco smoking is associated with reduction of p53, a tumour suppressor gene [32,33] which is considered “the genome guardian”. Suppression of T-cell responses by nicotine and tar is associated with decreased surveillance for tumour cells [28]. El-Zayadi et al. [24] reported that heavy smokers accumulate excess iron in hepatocytes which induces fibrosis and favours development of HCC. Smoking is considered a co-factor with HBV and HCV for hepatocarcinogenesis [34]. In addition, suppressed mood, a common feature among heavy smokers, increases the risk for development of cancer [25].

SMOKING AND LIVER CELL INJURY AMONG CHRONIC HEPATITIS C PATIENTS

El-Zayadi et al. [26] have reported an association between heavy smoking and liver cell injury in the form of necroinflammation, apoptosis and excess iron deposition in the liver. These effects are attributed to iron overload with consequent iron deposition in hepatocytes [20,34]. Excess hepatic iron induces oxidative stress and lipid peroxidation [11,14]. However, iron overload will not correct itself and the only exit of iron from the body is by bleeding or frequent chelation [19]. Therapeutic phlebotomy allows excess iron to be removed from the body and chelation of labile iron from the liver.

SMOKING AND THE RESPONSE TO IFN THERAPY AMONG CHRONIC HEPATITIS C PATIENTS

El-Zayadi et al. [35] reported that smokers suffering from chronic hepatitis C tend to have a lower response rate to IFN therapy. Therapeutic phlebotomy among chronic hepatitis C patients improves the response rate to IFN therapy [37,38]. Furthermore, the authors recommended that chronic hepatitis C patients should be advised to avert smoking before embarking on IFN therapy [39].

Several mechanisms have been implemented in resistance to IFN therapy in heavy smokers which are summarized in Figure 2. First, heavy smoking causes immunosuppression [22] such as reduction in CD4+ cells, impaired NK cytotoxic activity [27] and recognition of virus-infected cells, and induces apoptosis of lymphocytes [26]. Second, heavy smoking increases hepatic iron overload which is involved in resistance to IFN [20]. Third, smoking induces pro-inflammatory cytokines (IL-1, IL-6, TNF-α) [35] that mediate necroinflammation and steatosis. Fourth, smoking directly modifies IFN-α-activated cell signaling and action [19].

The present article sends a message indicating that smoking is an underestimated risk factor for liver disease. In this respect, further well-designed studies are needed to clarify this issue.
