Functional ANOVA with Multiple Distributions: Implications for the Sensitivity Analysis of Computer Experiments

Emanuele Borgonovo∗ and Max D. Morris† and Elmar Plischke‡

December 19, 2017

Abstract

The functional ANOVA expansion of a multivariate mapping plays a fundamental role in statistics. The expansion is unique once a unique distribution is assigned to the covariates. Recent investigations in the environmental and climate sciences show that analysts may not be in a position to assign a unique distribution in realistic applications. We offer a systematic investigation of existence, uniqueness, orthogonality, monotonicity and ultramodularity of the functional ANOVA expansion of a multivariate mapping when a multiplicity of distributions is assigned to the covariates. In particular, we show that a multivariate mapping can be associated with a core of probability measures that guarantee uniqueness. We obtain new results for variance decomposition and dimension distribution under mixtures. Implications for the global sensitivity analysis of computer experiments are also discussed.

Keywords: Computer Experiments; Functional ANOVA; Mixtures; Global Sensitivity Analysis.

1 Introduction

The functional ANOVA expansion [24] plays a central role in the design and analysis of computer experiments [75]. It provides the mathematical background of modern approaches to statistical inference in computer experiments [51]. One of the key premises to the current use of functional ANOVA-based methods is the unique distribution assumption: We assume to have information about the factors’ probability distribution, either joint or marginal, with or without correlation, and that this knowledge comes from measurements, estimates, expert opinion, physical bounds, output from simulations, analogy with factors for similar species, and so forth [24, p. 704]. With this assumption, we obtain a unique functional ANOVA expansion and, consequently, a unique set of the associated sensitivity measures.

However, lack of data, measurement errors, or expert disagreement may prevent analysts from assigning a unique distribution to the model inputs. Millner et al. report that researchers have assigned nineteen different distributions to climate sensitivity in alternative scientific investigations of the past ten years [48]. Gao et al. show high variability in computer experiments performed under alternative scenarios [26]. Paleori and Confalonieri test robustness of sensitivity results for uncertainty in distribution using the WARM model as a case study [57]. They show that uncertainty in distribution causes an overturn of the most important variables in 22% of the cases. These are not the first works dealing with the robustness of a sensitivity analysis results to the choice of the model input distributions. Early on, Chick discusses the use of two-stage distributions in simulation experiments [19]. Hu et al. studies uncertainty quantification on a well known climate model under uncertainty in distribution [31]. The work

‡Institut für Endlagerforschung, Technische Universität Clausthal, Adolph-Roemer-Str. 2a, 38678 Clausthal-Zellerfeld, Germany (elmar.plischke@tu-clausthal.de)
of Beckman and McKay is possibly the first work discussing the stability of sensitivity analysis results for perturbations in the model input distributions [8]. As Saltelli et al. underline, the use of multiple distributions may controversial [73]. Nonetheless, it has become a de-facto part of several studies and is frequently adopted.

Our purpose is to offer a systematic investigation of the impact of removing the unique distribution assumption on the classical functional ANOVA expansion of a multivariate mapping. We consider two paths that emerge from current and past practices. The starting datum is that the analyst posits a set \( \mathcal{M} = \{ \mu_1(x), \mu_2(x), \ldots, \mu_Q(x) \} \) of plausible model input distributions. In the first path, the analyst evaluates the model for each distribution in \( \mathcal{M} \) separately and obtains sensitivity measures for each distribution — without-prior path, henceforth. In the second path, the analyst assigns a prior over the the distributions in \( \mathcal{M} \) — with-prior path henceforth. For each path, we investigate six relevant notions: existence, uniqueness, orthogonality, monotonicity, ultramodularity, variance decomposition and dimension distribution. We study the implications in light of three sensitivity analysis settings: factor prioritization, trend identification and interaction quantification.

Let us report some of the findings. In both paths, existence is ensured if all the posited measures are compatible with the functional ANOVA expansion of the input output mapping. Regarding uniqueness, in the without-prior path the analyst is dealing with as many functional ANOVA expansions as many are the cores in \( \mathcal{M} \). A core is defined as a set of probability measures that lead to identical expansions. Thus, one has uniqueness if all the posited measures belong to the same core. In the with-prior path, one regains uniqueness: a multivariate mapping can be uniquely represented as the mixture of functional ANOVA expansions. Regarding orthogonality, in the without-prior path it is preserved. In the with-prior path, mixtures of classical functional ANOVA effects are not orthogonal with respect to the mixture of the distributions in \( \mathcal{M} \). Regarding monotonicity and ultramodularity, in the without-prior path these properties are preserved by the first order effects of the classical functional ANOVA expansion under each measure in \( \mathcal{M} \), as shown in previous literature [5]. In the with-prior path, we show that they are still preserved by the mixture of first order functional ANOVA effects.

Regarding variance decomposition and dimension distribution, in the without-prior path, the multiplicity of variance decompositions and of dimension distributions equals the cardinality of \( \mathcal{M} \). Conversely, variance decomposition and dimension distribution regain uniqueness in the with-prior path. The variance can be decomposed as the sum of two terms, a structural term equal to the mixture of variance decompositions and a second generated by the variability of the model output across the measures in \( \mathcal{M} \). We analyze the question of whether there are conditions under which an analyst can proceed ignoring the presence of multiple distributions. Our analysis shows that in a trend identification setting, monotonicity of the input-output mapping is a sufficient condition for the indications about trend obtained under one measure to remain the same under any other measure in \( \mathcal{M} \). The same does not apply for factor prioritization and interaction quantification where the analyst needs to deal with a multiplicity of sensitivity measures, unless she(he) posits a prior. Then, the question is how to deal with such multiplicity. Formalizing the approach in [26], we propose a robust extension of the sensitivity settings of [74] and illustrate their application through a case study.

The remainder of the paper is organized as follows. Section 2 presents a literature review. Section 3 discusses the functional ANOVA expansion in the without-prior path and introduces the notion of functional ANOVA core. Section 4 addresses the with-prior path, discussing uniqueness, monotonicity, orthogonality and ultramodularity. Section 5 addresses variance decomposition and dimension distribution in the without-prior and with-prior paths. Section 6 offers a twofold discussion, focusing first on decision-theoretical aspects and then on the link between the mixture functional ANOVA decomposition and the generalized functional ANOVA expansion [10] [63]. Section 7 discusses numerical aspects and presents an application. Section 8 concludes the work.
2 Functional ANOVA and Related Concepts: A Review

The functional ANOVA expansion of a multivariate mapping originates with the works of [25] and [31], and is definitively established with the well known proofs of [24], [78] and [60] (see [54, p. 1] for a detailed historical account).

Applications of the functional ANOVA expansion are numerous. Without any exhaustiveness claim, we recall its role in the study of quasi-Monte Carlo integration methods, where it is applied to various notions of the effective dimension of an integrand [54] and in dimension reduction in high-dimensional problems in finance [51]. It is fundamental for smoothing spline ANOVA models [52, 29, 42, 15], as well as for generalized regression models [26, 47, 39]. It is also used in conjunction with metamodelling methods, such as Gaussian metamodeling [51], polynomial chaos expansion [65, 10, 30, 50] and polynomial dimensional decomposition [61]. The latter finds applications in multi-scale fracture mechanics [64], random eigenvalue problems [65], and stochastic design optimization [65].

Regarding the mathematical framework, one writes the input-output mapping as

\[ g : \mathcal{X} \rightarrow \mathbb{R}, \]

where \( \mathcal{X} \subseteq \mathbb{R}^n \) and \( n \) is the number of inputs. Under uncertainty, we denote the input probability space by \((\mathcal{X}, \mathcal{B}(\mathcal{X}), \mu)\), where \( \mu : \mathcal{B}(\mathcal{X}) \rightarrow [0,1] \) represents the input probability distribution. Uncertainty in the input causes the model output to become a function of random variables, \( G = g(\mathbf{X}) \).

Consider now the set \( Z = \{1, 2, \ldots, n\} \) of the \( n \) model input indices, and let \( 2^Z \) denote the associated power set. In the remainder, \( z \in 2^Z \) denotes a generic subset of indices. Throughout the work, we assume that \( g \in L^2(\mathcal{X}, \mathcal{B}(\mathcal{X}), \mu) \) and that \( d\mu(x) = \prod_{i=1}^n d\mu(x_i) \), unless noted otherwise.

**Proposition 1 [24]** Under the above assumptions, \( g \) can be integrally expanded as the sum of \( 2^n \) effects

\[ g(\mathbf{x}) = \sum_{z \in 2^Z} g_z^*(\mathbf{x}_z), \]

where

\[ g_0^0 = g_0^0 = \mathbb{E}_\mu[G] = \int_\mathcal{X} g(\mathbf{x})d\mu(\mathbf{x}), \quad g_z^0(\mathbf{x}_z) = \int_{\mathcal{X} \setminus z} g(\mathbf{x})d\mu(\mathbf{x} \setminus z) - \sum_{v \subset z} g_v^0(\mathbf{x}_v), \]

\[ d\mu(\mathbf{x} \setminus z) = \prod_{i \notin z} d\mu(x_i) \quad \text{and} \quad \mathcal{X} = \mathcal{X}_z \times \mathcal{X}_{\setminus z}, \quad \mathcal{X}_z \subseteq \mathbb{R}^{|z|}, \quad \mathcal{X}_{\setminus z} \subseteq \mathbb{R}^{n-|z|}. \]

The function \( g_z^0(\mathbf{x}_z) \) is called effect function of order \( k \), where \( k = |z| \) is the cardinality of the index set \( z \). It refers to the residual interaction of the inputs whose indices are in \( z \). In Proposition 1, \( \mu \) is a product measure. The effect functions satisfy the following conditions named strong annihilating conditions in [63]:

\[ \int g_z^0(\mathbf{x}_z)d\mu(x_i) = 0 \quad \text{for} \quad i \in z \quad \text{and} \quad z \neq \emptyset. \]

These conditions imply that the effect functions have null expectation and are orthogonal, i.e.,

\[ \mathbb{E}_\mu[g_z^0(\mathbf{X}_z)] = 0 \quad \text{for all} \quad z \neq 0, \quad \text{and} \quad \mathbb{E}_\mu[g_z^0(\mathbf{X}_z)g_{z'}^0(\mathbf{X}_{z'})] = 0 \quad \text{for all} \quad z'' \neq z'. \]

In the remainder, also the conditional expectations are of interest, i.e., the non-orthogonalized effect functions

\[ w_z^0(\mathbf{x}_z) = \mathbb{E}_\mu[G|\mathbf{X}_z = \mathbf{x}_z] = \sum_{v \subseteq z} g_v^0(\mathbf{x}_v). \]

One then obtains the decomposition of the variance of \( G \) in \( 2^n - 1 \) terms following the steps in [24, 77]. In particular, by subtracting \( g_0^0 \) from both sides, squaring, and taking the expectation we obtain

\[ \mathbb{E}_\mu[(g(\mathbf{X}) - g_0^0)^2] = \mathbb{E}_\mu\left[ \sum_{z \in 2^Z, z \neq \emptyset} (g_z^0(\mathbf{X}_z))^2 \right]. \]
The variance of $g(X)$, $\mathbb{V}[G]$. Then, as a consequence of the conditions in (5), we have
\[
\mathbb{V}[G] = \sum_{x \in 2^z, x \neq \emptyset} \int_{\mathcal{X}_z} [g^T(x_z)]^2 d\mu(x_z).
\] (8)

In summary, we have the following result.

Proposition 2 [24] [77] The variance of $G$ under $\mu$, $\mathbb{V}[G]$, can be written as:
\[
\mathbb{V}[G] = \sum_{x \in 2^z, x \neq \emptyset} V^T_{\mu} \text{ where } V^T_{\mu} = \int_{\mathcal{X}_z} [g^T(x_z)]^2 d\mu(x_z).
\] (9)

The term $V^T_{\mu}$ represents the portion of $\mathbb{V}[G]$ caused by the interactions of the inputs with indices in $z$. The variance decomposition in (9) is the basis for the definition of variance-based sensitivity indices, which are obtained by normalizing $V^T_{\mu}$ [32] [77].

\[
S^T_{\mu} = V^T_{\mu} / \mathbb{V}[G].
\] (10)

The quantity $S^T_{\mu}$ is called the variance-based sensitivity index of group $z$ for all $z \in 2^z$, $z \neq \emptyset$.

In the formal parts of this work, we shall use the non-normalized version of the indices $V^T_{\mu}$, for notational simplicity. We shall use the normalized version $S^T_{\mu}$ in numerical experiments/examples. The literature has placed particular emphasis on the first and total order sensitivity indices, defined respectively as
\[
V^T_{i} = V^T_{(i)} \text{ and } VT^T_{i} = \sum_{z : i \in z, z \neq \emptyset} V^T_{z}.
\] (11)

The quantities $V^T_{\mu}$ and $VT^T_{\mu}$ are the individual and the total contribution of $X_i$ to the variance of $G$.

The estimation of variance-based sensitivity measures has been subject of intensive studies since the late 1990’s and is still an active field of research [55] [56]. Indeed, the highest computational cost for estimation of all variance-based indices is $C_{all} = (2^n - 1)N_{in}N_{out}$, where $N_{in}$ and $N_{out}$ are the sample sizes required for the inner and outer loops of model evaluation associated with a brute force estimation. However, the Extended FAST approach of [76] allows us to obtain first and total order indices at a cost proportional to $nN_r$, where $N_r$ is an appropriate number of replicates. The pick and freeze design developed in the works of Sobol’ [73], Homma and Saltelli [32], and its amelioration in [69] and [10] allows the estimation of all first and total order effects at a cost of $N(n + 2)$ model runs, where $N$ is the basic sample size. The random balance design, a variant of the FAST method introduced in [21], enables the estimation of first order sensitivity indices at a nominal cost of $N$ model runs. This is the same computational cost of a so-called given data estimation. A given data estimation computes global sensitivity measures from the sample available after an uncertainty quantification. That is, one generates a sample of size $N$ for uncertainty quantification and then the same sample is used to estimate global sensitivity measures. Due to space constraints, we cannot give a detailed formulation of the given data approach and we refer the interested reader to [69] [59] [10] for further details. The COSI method introduced in [55] is a variant of the FAST method that permits the estimation of first order sensitivity indices from the sample generated for an uncertainty quantification. These approaches encounter limitations when the estimation of higher order indices is of interest. To this purpose, a strategy in which the $N$ model runs are used to fit a metamodel and then the metamodel is used to estimate sensitivity indices may be more effective. Subroutines based on polynomial chaos expansion [60] [24], polynomial dimensional decomposition [62], smoothing spline ANOVA models [66] [67], sparse grid interpolation [13] are available and have found application in several disciplines. Most of these subroutines allow the analyst to obtain estimates of higher order and total order indices. Moreover, they allow the estimation and graphing of first and second order effects of the functional ANOVA expansion.

We conclude this review with the process of making inference in sensitivity analysis. This process is made systematic through the concept of sensitivity analysis setting — see [24] and [11]. In a factor prioritization, we are asked to bet on the input that, if determined
functions are \[ a) \] Owen’s mass function, defined by \( \Pr(T_\mu = z) = V_\mu^T/\mathbb{V}_\mu[G] = S_\mu^V \);
\( b) \) dimension distribution of \( g \) in the superimposition sense the distribution of the cardinality of \( T_\mu, |T_\mu| \), where \( T_\mu \) is the random variable associated with Owen’s mass function, and
\( c) \) dimension distribution of \( g \) in the truncation sense, the distribution of \( \max\{j : j \in \mathbb{Z}\} \).

Owen \[54\] then defines the effective dimensions in the superimposition and truncation sense, respectively, as the mean values of \( |T| \) and of \( \max\{j : j \in \mathbb{Z}\} \), i.e., as
\[
D_S^\mu = \sum_{|z| > 0} |z| \Pr(T_\mu = z) = \sum_{i=1}^n VT_\mu^i,
\]
\[
D_T^\mu = \sum_{|z| > 0} \max\{j : j \in \mathbb{Z}\} \Pr(T_\mu = z),
\]
respectively. To illustrate, a mean effective dimension in the superimposition sense equal to unity indicates the absence of interactions. Note also that the mean effective dimension is equal to the sum of total effects, as in this sum a \( k^{th} \) order effect is counted \( k \) times. Regarding interaction quantification, the higher the value of \( D_S^\mu \) or \( D_T^\mu \), the higher the relevance of interactions.

3 Existence, Multiplicity and Robustness

The discussion in Section 2 shows that all the notions and quantities related to a functional ANOVA expansion are conditional on the distribution \( \mu \). In this section, we analyze the consequences of removing the unique distribution assumption. To fix ideas, suppose that the analyst is uncertain among \( Q \) possible model input distributions. The need to consider these \( Q \) distributions may come from lack of data or simply by the fact that the analyst is considering a set of measures that represent a perturbation of a reference distribution that she(he) has assigned to the inputs. In either case, the analyst is positing a set \( \mathcal{M} \) of probability measures. The set \( \mathcal{M} \) does not appear in traditional sensitivity studies of computer experiments. \( \mathcal{M} \) might be a countable (possibly infinite) or uncountable set. The first case occurs if the decision-maker assigns a discrete number (say \( Q \)) of second order probability models. The second case occurs, for instance, in applications where the decision-maker assigns a first order distribution depending on some parameters and then a continuous second order distribution over the parameters. Each measure \( \mu^m \in \mathcal{M} \) is associated with a potentially different functional ANOVA expansion. To illustrate, consider the next example.

Example 1 A traditional test case in sensitivity analysis is the Ishigami test function \[53\]:
\[ g = \sin(x_1) \left(1 + bx_1^4\right) + a \sin^2(x_2). \]  
\[ (14) \]
The base case distribution is \( \mu^1 : X_1, X_2, X_3 \sim \mathcal{U}[-\pi, \pi], \) i.i.d. Then, the non-vanishing effect functions are \[57\]:
\[ g_0^1 = \frac{a}{2}; \ g_1^1 = \sin(x_1) \left(1 + b\frac{x_1^4}{5}\right); \ g_2^1 = a \sin^2(x_2) - \frac{a}{2}; \ g_{1,3}^1 = b \sin(x_1) \left(x_3^4 - \frac{\pi^4}{5}\right). \]  
\[ (15) \]
Due to lack of knowledge or just to test the conclusions under alternative distributions, the analyst then evaluates two alternative assignments. The second assignment is \( \mu^2 : X_1, X_2, X_3 \sim \mathcal{N}(0,1), \) i.i.d. Then, the non-vanishing effects of the ANOVA decomposition are:
\[ g_0^2 = \frac{a}{2} \left(1 - e^{-2}\right); \ g_1^2 = \sin(x_1) \left(1 + 3b\right); \ g_2^2 = a \sin^2(x_2) - \frac{a}{2} \left(1 - e^{-2}\right); \ g_{1,3}^2 = b \sin(x_1) \left(x_3^4 - 3\right). \]  
\[ (16) \]
As a third assignment, she(he) sets \( \mu^3 : X_1, X_2, X_3 \sim U[0, \pi] \), i.i.d., obtaining the following effect functions:

\[
\begin{align*}
  g_0^3 &= \frac{a}{2} + \frac{2}{\pi} \left( 1 + \frac{\pi^4}{5} \right); \quad g_1^3 = \left( \sin(x_1) - \frac{2}{\pi} \right) \left( 1 + b \frac{\pi^4}{5} \right); \quad g_2^3 = a \sin^2(x_2) - \frac{a}{2} \\
  g_3^3 &= \frac{2b}{\pi} \left( x_3^4 - \pi^4 x_3 \right); \quad g_{13}^3 = b \left( \sin(x_1) - \frac{2}{\pi} \right) x_3^4 - \pi^4/5.
\end{align*}
\]

(17)

Note that the effect function \( g_3^3(x_3) \) is now non-null and that \( g_2^3 = g_2^1 \).

In general, the set of probability measures that an analyst can posit is the uncountable set of all distributions on measurable space \((X, \mathcal{B}(X))\). However, such assignment might be either too vast (some distributions would not reflect the analyst’s state of knowledge), or, even, incompatible with the functional ANOVA expansion of \( g \). In particular, an analyst’s degree of belief about the model inputs is consistent with the functional ANOVA expansion of the output only if \( g \) is measurable with respect to all the assigned distributions. We then let

\[
\Psi[g] = \left\{ \mu : g \in L^2(X, \mathcal{B}(X), \mu) \land d\mu = \prod_{i=1}^n d\mu_i \right\}
\]

(18)
denote the set of all probability measures on \((X, \mathcal{B}(X))\) compatible with the functional ANOVA expansion of \( g \). For non-triviality, in the remainder, we assume that the posited set \( \mathcal{M} \) is a subset of \( \Psi[g] \).

Then, let us investigate how many distinct functional ANOVA expansions are possible for a multivariate mapping. In the next definition, consider \( z = \{i_1, i_2, \ldots, i_k\} \) and let \( X_z = X_{i_1} \times X_{i_2} \times \ldots X_{i_k} \).

**Definition 1** The set \( C \subseteq \Psi[g] \) is called a core of measures for the functional ANOVA expansion of \( g \) on \((X, \mathcal{B}(X))\) if

\[
g_{\mu'}(x_z) = g_{\mu''}(x_z)
\]

(19)

for all \( \mu', \mu'' \in C \), for all \( z \in 2^Z \) and for all \( x_z \in X_z \) such that \( d\mu'(x_z) \neq 0 \), \( d\mu''(x_z) \neq 0 \).

Equation (19) suggests that two probability measures in \( \Psi[g] \) belong to the same core if they lead to the same functional ANOVA expansion of \( g \). The condition \( d\mu'(x_z) \neq 0 \), \( d\mu''(x_z) \neq 0 \) is technical and takes into account the situation in which the distributions differ in their support \( X \). This situation might emerge if \( \mu' \) is absolutely continuous with respect to \( \mu'' \). In that case, comparing \( g_{\mu'}(x_z) \) and \( g_{\mu''}(x_z) \) is meaningful only if \( x_z \) belongs to the support of both \( \mu' \) and \( \mu'' \).

A functional ANOVA core can either contain a unique measure or a multiplicity of measures. However, the same measure \( \mu \) cannot belong simultaneously to two cores. Then, \( \Psi[g] \) is partitioned by its cores (please refer to Appendix A for all proofs).

**Proposition 3** Let \( \Psi[g] \) be the set of all probability measures compatible with the functional ANOVA expansion of \( g \). Let \( C_x \) denote a generic core. Then \( \Psi[g] = \cup C_x \), where \( C_x \) is a functional ANOVA core of \( \Psi[g] \) and \( C_x \cap C_j = \emptyset \). Moreover, given \( M \subseteq \Psi[g] \), let \( C^M_x = M \cap C_x \). Then, \( M = \cup C^M_x \) and \( C^M_x \cap C^M_y = \emptyset \).

Proposition 8 allows us to characterize the multiplicity of functional ANOVA expansions that an analyst is dealing with once \( M \) is posited: \( g \) possesses as many functional ANOVA representations as there are cores in which \( M \) is partitioned.

The determination of cores is not straightforward. Also, one would expect an infinity of cores if \( M \) is uncountable. However, the next example illustrates a class of functions for which cores can be readily identified.

**Example 2** Suppose that the input-output mapping can be written as a composite linear function

\[
g(x) = \sum_{u \in 2^X, i \in u} t_i(x_i).
\]

Then, given \( M = \{\mu, \mu'\} \) (inducing random vectors \( X \) and \( X' \)) with propagated output random variables \( G = g(X) \) and \( G' = g(X') \) the ANOVA expansions of \( G \) and \( G' \) coincide if \( \mathbb{E}_\mu[t_i(X_i)] = \mathbb{E}_{\mu'}[t_i(X'_i)] \). Hence, if \( C \) is any family of distributions such that \( \mathbb{E}_\mu[t_i(X_i)] = \mathbb{E}_{\mu'}[t_i(X'_i)] \) for all \( \mu, \mu' \in C \) then \( C \) is a core.
The Ishigami function in Example 1 is of the form in (20) and can be rewritten as $g = t_1(x_1) t_2(x_2) + t_2(x_2)$, with $t_1(x_1) = \sin(x_1)$, $t_2(x_2) = \sin^2(x_2)$ and $t_3(x_1) = (1 + b x_1^2)$. Consider the following three model input distributions: $\mu^1$ as in Example 1 $\mu^1 : X_1, X_3 \sim U[-\pi, \pi]$, $X_2 \sim U[-\frac{\pi}{2}, \frac{\pi}{2}]$, and $\mu^2 : X_1, X_2 \sim U[-\frac{\pi}{2}, \frac{\pi}{2}]$, $X_3 \sim U[-\pi, \pi]$. Then, $E_{\mu^1}[G_i] = E_{\mu^2}[G_i]$ for $i = 1, 2, 3$ and $x_1, x_2, x_3 \in [-\frac{\pi}{2}, \frac{\pi}{2}]$. Thus, $\mu^1$, $\mu^2$ and $\mu^3$ belong to the same core. In the special case in which $t_i(X_i) = X_i$ for all $i = 1, 2, ..., n$, two distributions assigning the same expectations to the model inputs are in the same core. The question is whether there are indeed models for which a multilinear approximation holds. In that respect, uncertainty in distribution is a relevant topic in reliability analysis and risk assessment of complex technological systems [3]. As it is well known, the mapping in probabilistic risk assessment models is multilinear as a function of basic event probabilities. Then, for this class of problems functional ANOVA cores are families of distributions that lead to the same expected values of the model inputs. However, this is not the case in general. To illustrate, the strain model $g(x) = x_1 x_2^2$ in solid mechanics does not satisfy the composite multilinearity assumption. We therefore do not rely further on such assumption in the remainder of the present investigation.

4 Multiple Distributions and a Prior

We now discuss the with-prior path. Under uncertainty in distribution, best practices recommend the use of a two-stage sampling procedure [10]. In order to apply the procedure, the analyst needs to assign a prior $P_\mu$ over the component measures $\mu^m$ in $\mathcal{M}$. In this section, we deal with the technical aspects that emerge after such assignment. We start with the probability spaces. Let $\mathcal{F}(\mathcal{M})$ denote the $\sigma$-algebra generated by all maps $\mu \mapsto \mu(A)$ for each $A \in \mathcal{B}(Y)$ and for each $\mu \in \mathcal{M}$, giving rise to the measurable space $(\mathcal{M}, \mathcal{F}(\mathcal{M}))$. The corresponding probability space is $(\mathcal{M}, \mathcal{F}(\mathcal{M}), P_\mu)$, and $P_\mu : \mathcal{F}(\mathcal{M}) \to [0, 1]$. Note that, because the algebra generated by $\mathcal{M}$ is included in the algebra generated by $\Psi[g]$, the following are equivalent: a) assigning the prior directly on $(\Psi[g], \mathcal{F}(\Psi[g]))$ or b) using $(\mathcal{M}, \mathcal{F}(\mathcal{M}))$ and assigning $P_\mu$ equal to zero on $\Psi[g] \setminus \mathcal{M}$. Hence, for notation simplicity, in the remainder, the symbol $\mathcal{M}$ can be used without loss of generality. In the case $\mathcal{M}$ is uncountable, we have to assume a density $dP_\mu(\mu)$, so that the expectations are written as $E_{P_\mu}[g] = \int_\mathcal{M} E_{P_\mu}[g]dP_\mu(\mu) = \int_\mathcal{M}[\int_\mathcal{X} g(x) d\mu(x)]dP_\mu(\mu)$. In the finite or countable case, $\mathcal{M}$ is of the type $\mathcal{M} = \{\mu^1, \mu^2, ..., \mu^M\}$, and $P_\mu$ is a sequence of non-null numbers $p_m$, such that $\sum_{m=1}^M p_m = 1$ and $E_{P_\mu}[g] = \sum_{m=1}^M p_m E_{\mu^m}[g] = \sum_{m=1}^M p_m \int_\mathcal{X} g(x)d\mu^m(x)$. For simplicity, we will use this discrete notation in the remainder.

We start analyzing independence and uniqueness. First, one needs to observe that assigning a prior $P_\mu$ implies that the analyst’s uncertainty about the model inputs is represented by the mixture

$$\mu(x) = \sum_{m=1}^Q p_m \mu^m(x), \quad (21)$$

where the weights are determined by $P_\mu = \{p_1, p_2, ..., p_Q\}$, $Q \in \mathbb{N}$, with $p_m > 0$ and $\sum_{m=1}^Q p_m = 1$. Regarding independence, even if under each individual $\mu^m$ in (24) the model inputs are independent, under the mixture $\mu$ they are not. In particular, we find:

$$\text{Cov}(X_i, X_j) = \sum_{m=1}^Q p_m E_{\mu^m}[X_i] E_{\mu^m}[X_j] - E[X_i] E[X_j], \quad (22)$$

where $E[X_i] = \int_\mathcal{X} x_i d\mu(x)$ and $E_{\mu^m}[X_i] = \int_\mathcal{X} x_i d\mu^m(x)$, $i = 1, 2, ..., n$. By (22) Cov$(X_i, X_j)$ is in general not null. However, it becomes null if $E_{\mu^m}[X_i] = E_{\mu^m}[X_j]$ for all $m, t = 1, 2, ..., Q$. That is, if there is agreement about the expected value of the model inputs, then the model inputs remain uncorrelated, albeit, in principle, not independent. More generally, we observe that the mixture in (21) implies that independence holds conditionally on $\mu = \mu^m$. This situation resembles de Finetti’s exchangeability (23) in so far as exchangeable random variables are independent conditionally on the value of a parameter.

We now prove that, within a two-stage sampling procedure, the functional ANOVA expansion regains uniqueness. We consider here two alternative routes for exploring sensitivity within a two-stage sampling procedure. A third approach is discussed in Section 6. The first
Example 3 continued. The assigned distributions imply different supports for the model inputs. Introducing the following indicator function $I_{[a,b]} = \begin{cases} 1 & \text{if } a \leq x \leq b \\ 0 & \text{otherwise} \end{cases}$, we can write the three distributions in Example 1 as

$$g(x) = \sum_{\alpha \in \mathcal{Z}} g_\alpha^a(x),$$

(23)

where

$$g_\alpha^a = \sum_{m=1}^Q p_m g_m^a \quad \text{and} \quad g_\alpha^a(x_i) = \mathbb{E}_{P_\alpha}[g_\alpha^a(x_i)] = \sum_{m=1}^Q p_m g_m^a(x_i).$$

(24)

We call:

1) the expansion $\sum_{\alpha \in \mathcal{Z}} g_\alpha^a(x_i)$ at the right hand side of (23) mixture functional ANOVA expansion of $g$;

2) the summands $g_\alpha^a(x_i)$ mixture effect functions.

The next example illustrates Proposition 4.

Example 4. Given a prior $(\mathcal{M}, \mathcal{F}(\mathcal{M}), P_\mu)$ and a measurable function $g : \mathcal{X} \to \mathbb{R}$, $g \in L^2(\mathcal{X}, \mathcal{B}(\mathcal{X}), \mu^m)$, then

$$g(x) = \sum_{\alpha \in \mathcal{Z}} g_\alpha^a(x),$$

(23)

where

$$g_\alpha^a = \sum_{m=1}^Q p_m g_m^a \quad \text{and} \quad g_\alpha^a(x_i) = \mathbb{E}_{P_\alpha}[g_\alpha^a(x_i)] = \sum_{m=1}^Q p_m g_m^a(x_i).$$

(24)

We call:

1) the expansion $\sum_{\alpha \in \mathcal{Z}} g_\alpha^a(x_i)$ at the right hand side of (23) mixture functional ANOVA expansion of $g$;

2) the summands $g_\alpha^a(x_i)$ mixture effect functions.

Thus, at the intersection of the supports, i.e., for $x \in [0,\pi]^3$, we have

$$g_\alpha(x) = \alpha + \frac{1}{3} \left( \frac{2}{\pi} \right) \left( 1 + b \frac{\pi^4}{5} \right) - \frac{a}{6} e^{-2};$$

$$g_\alpha^a(x_1) = \frac{I_{[0,\pi]}(x_1)}{3} \sin(x_1) \left[ \left( 1 + \frac{\pi^4}{5} \right) + \sin(x_1) \left( 1 + 3b \right) \frac{2}{3} \right];$$

$$g_\alpha^a(x_2) = \frac{I_{[0,\pi]}(x_2)}{3} \left( \sin(x_2) - \frac{a}{2} \right) \left( 1 + 2 \frac{\pi^4}{5} \right) + \frac{I_{[0,\pi]}(x_2)}{3} \left( a \sin^2(x_2) - a/2 \right) \left( 1 - e^{-2} \right) \frac{a}{2};$$

$$g_\alpha^a(x_3) = \frac{I_{[0,\pi]}(x_3)}{3} \left( x_3 - \frac{\pi^4}{5} \right);$$

$$g_\alpha^{a,b}(x_1, x_2) = \frac{I_{[0,\pi]}(x_1)}{3} \frac{I_{[0,\pi]}(x_2)}{3} \sin(x_1) \left[ \left( x_3 - \frac{\pi^4}{5} \right) + \frac{b \sin(x_1) (x_3 - 3)}{3} \right] + \frac{I_{[0,\pi]}(x_1)}{3} \frac{I_{[0,\pi]}(x_2)}{3} \left( \sin(x_1) - \frac{2}{\pi} \right) \left( x_3 - \frac{\pi^4}{5} \right).$$

Note that the sum of the mixture effect functions equals the original mapping at any point $x \in \mathbb{R}^3$. 
The second route is as follows. The analyst wishes to perform the functional ANOVA expansion using $\mu_X$ as probability measure and computes the mixture effect functions from:

$$
g_0^X = \mathbb{E}_\mu^X[G] = \int_X g(x) d\mu_X, \quad g_2^X(x_3) = \int_{X_{-3}} g(x_1, x_2, x_3) d\mu_{X_{-3}}(x_{-3}) - \sum_{\emptyset \subsetneq z} g_0^z(x_z), \quad (27)$$

where

$$
\mu_{X_{-z}}(x_{-z}) = \int_{X_z} \mu_X(x) dx_z \quad (28)
$$

is the marginal distribution of $X_{-z}$. Then, the following proposition shows that both routes lead to the same result.

**Proposition 5** For a measurable function $g$ it holds that $\mathbb{E}_\mu^X[G] = \mathbb{E}_{P_m}[G] = \sum_{m=1}^Q P_m g_m^n$ and $g_2^X(x_3) = g_2^P(x_3)$ so that $g(x) = \sum_{v \subseteq z} g_v^X(x_v) = \sum_{v \subseteq z} g_v^P(x_v)$.

Propositions 4 and 5 suggest that we obtain the same functional ANOVA expansions by either of the following two routes:

1. We get the functional ANOVA decomposition of $g$ under each of the measures in $M$ and then mix the decompositions using weights determined by $P_m$;
2. We decompose $g$ using (27) and (28).

If we leave the sensitivity framework for a more general perspective, Propositions 4 and 5 suggest a representation theorem for a multivariate mapping. Given a set of measures $M \in \Psi[g]$ and a prior $P_m$, a measurable multivariate mapping can be uniquely projected onto $2^n - 1$ mixture effect functions.

The next example illustrates the second route by means of our running example.

**Example 4** For notation simplicity, let us denote the Ishigami model as a generic three-variate mapping $g(x) = g(x_1, x_2, x_3)$, $g: \mathbb{R}^3 \to \mathbb{R}$. Also, let us denote the three joint model input distributions in Example 1 as $\mu^3_2(x) = \mu^{x_1}(x_1) \mu^{x_2}(x_1) \mu^{x_3}(x_1)$, $m = 1, 2, 3$. To illustrate calculations, we focus on the first order mixture effect function of $x_1$. By (27) we write

$$
g_1^{P_m}(x_1) = \int \int g(x_1, x_2, x_3) f_2,3(x_2, x_3) dx_2 dx_3, \quad (29)$$

where, $f_2,3(x_2, x_3)$ is the joint marginal density of $X_2$ and $X_3$, $f_2,3(x_2, x_3) = f_X(x) dx_1$. Then, we have

$$
g_1^{P_m}(x_1) = \int \int \int g(x_1, x_2, x_3) f_2,3(x_2, x_3) dx_2 dx_3 = p_1 \int \int g(x_1, x_2, x_3) f_2(x_2) f_3(x_3) dx_2 dx_3 = p_1 g_1^{P_1}(x_1) + p_2 g_1^{P_2}(x_1) + p_3 g_1^{P_3}(x_1) = \sum_{m=1}^3 p_m g_1^{P_m}(x_1). \quad (30)$$

Let us now analyze the properties of the mixture effect functions, starting with orthogonality.

### 4.1 Orthogonality

Orthogonality is not preserved by the mixture of functional ANOVA terms with respect to $\mu_X(x)$ as reference distribution.

**Example 5 (Example 3 continued)** Consider the mixture integral over the first order mixture ANOVA effect function $g_i^P(x_3)$ from Example 3. Here,

$$
\mu(X_3) = \int \mu_X(x) dx_2 dx_1 = \frac{1}{3} \frac{1}{2\pi} I_{[-n, n]}(x_3) + \frac{1}{3} \phi(x_3) + \frac{1}{3} \frac{1}{2\pi} I_{[0, n]}(x_3). \quad (31)
$$

Then,

$$
\int g_i^P(x_3) d\mu_X(x_3) = \int \frac{1}{2\pi} \left( x_3^3 - \frac{x_3^4}{4} \right) \phi(x_3) \left( d\mu^1(x_3) + d\mu^2(x_3) + d\mu^3(x_3) \right) = \int \frac{1}{2\pi} \left( x_3^3 - \frac{x_3^4}{4} \right) d\mu^2(x_3) = \frac{1}{2\pi} \left( 1 - \frac{1}{8} \right) \neq 0. \quad (32)
$$

We observe that to obtain orthogonal components of the functional ANOVA expansion, one would need to resort to the generalized functional ANOVA expansion under correlations. This aspect is discussed in detail Section 6.
4.2 Monotonicity

In computer experiments, analysts are often interested in studying the trend of the output as the model inputs vary. Then, determining whether the output is monotonic with respect to the inputs becomes of interest. Let us recall the definition of monotonicity for a multivariate utility theory, game theory, and economics [43, 44, 47]. We show in Appendix B that results similar to the ones found for monotonicity hold for ultramodularity. Then, if a function is ultramodular, it is enough to study the behavior of the effect functions under a given \( µ^{m} \) and the qualitative insights hold for any other component measure in \( M \).

**Definition 2** Given \( g : \mathcal{X} \to \mathbb{R} \), we say that \( g \) is non-decreasing on \( \mathcal{X} \) if \( g \) is such that

\[
g(x^1) \leq g(x^2),
\]

for all \( x^1, x^2 \in \mathcal{X} \) with \( x^1 \leq x^2 \).

In the above definition, the inequality \( x^1 \leq x^2 \) is understood component-wise. If the strict inequality holds in (33), then one says that \( g \) is increasing. Under the unique distribution assumption, a set of results concerning monotonicity of the effect functions are proven in [5]. We synthesize the main findings in the following lemma.

**Lemma 1** If \( g \) is non-decreasing then:

1) all non-orthogonalized effect functions \( w^n_i(x_z) \) are non-decreasing;
2) all orthogonalized first order effect functions are non-decreasing;
3) Given \( \Delta x \geq 0 \), introduce for \( [x, x + \Delta x] \subset \mathcal{X} \) the functions

\[
\Delta w^n_i = w^n_i(x_z + \Delta x_i) - w^n_i(x_z),
\]

\[
\Delta g^n_i = g^n_i(x_z + \Delta x_i) - g^n_i(x_z).
\]

If the following condition holds:

\[
\Delta w^n_i \geq \sum_{z \subset x} \Delta g^n_z
\]

then all effect functions in (24) are non-decreasing.

Thus, the graphs of the first order effect functions provide visual indications about the monotonicity of \( g \). However, note that items 1 and 2 are not sufficient conditions. Thus, we infer from the behavior of \( g_i(x_z) \) that if any of the first order effect functions is not monotonic then \( g \) is not monotonic. To illustrate, in Example 1 the fact that \( g^{1+} \) is not monotonic suffices to state that the Ishigami function is not monotonic. Items 1 and 2 become if and only if conditions when the model is separable, i.e., additive or multiplicative — see [5] for further details. Item 3 states a sufficient condition for all higher order effect functions to retain the original monotonicity of \( g \). However, this condition is rather stringent and, in general, higher order effects do not retain the original monotonicity of \( g \).

Consider now the case in which the analyst has posited \( M \), but without a prior. The results in Lemma 1 hold for any component measure \( \mu^m \). Thus, if \( g \) is monotonic, the conditional expectations of \( g \) with respect to any group of model inputs as well as the first order effect functions are monotonic. That is, the results in Lemma 1 are robust to the choice of the probability measure.

The next result holds in the case in which the analyst assigns a prior and shows that the mixed effect functions retain the monotonicity properties that hold under a unique distribution.

**Proposition 6** Given \( (M, \mathcal{F}(M), P_{\mu}) \), if \( g \) is non-decreasing then:

1) the non-orthogonalized mixture effects \( w^n_i^\mu(x_z) \) of all orders are non-decreasing;
2) the orthogonalized mixture first order effects \( |g^n_i^\mu(x_z)| \) are non-decreasing;
3) Given \( \Delta x > 0 \), if for all \( \mu \in M \)

\[
\Delta w^n_i^\mu \geq \sum_{z \subset x} \Delta g^n_z^\mu
\]

then all effects in (24) are non-decreasing.

4.3 Ultramodularity

Ultramodularity is a generalization of scalar convexity and is a relevant property in multivariate utility theory, game theory, and economics [43, 44, 47]. We show in Appendix B that results similar to the ones found for monotonicity hold for ultramodularity. Then, if a function is ultramodular, it is enough to study the behavior of the effect functions under a given \( \mu^m \) and the qualitative insights hold for any other component measure in \( M \).
Table 1: Variance decomposition and effective dimension results for the Ishigami test function under the distributions of Example 1.

| Distribution | Contribution to Output Variance | Total Variance | Effective Dimension |
|--------------|---------------------------------|----------------|---------------------|
| $\mu_1$     | $V_{\mu_1}^\mu$ | 4.35 | 6.13 | 0 | 3.37 | $\|\mu_1\|_G = 13.84$ |
|              | $S_{\mu_1}^\mu$ | 0.31 | 0.44 | 0 | 0.24 | $D_S^\mu = 1.24$ |
| $\mu_2$     | $V_{\mu_2}^\mu$ | 0.73 | 5.90 | 0 | 0.41 | $\|\mu_2\|_G = 7.05$ |
|              | $S_{\mu_2}^\mu$ | 0.10 | 0.84 | 0 | 0.06 | $D_S^\mu = 1.05$ |
| $\mu_3$     | $V_{\mu_3}^\mu$ | 0.82 | 6.12 | 2.73 | 0.64 | $\|\mu_3\|_G = 10.32$ |
|              | $S_{\mu_3}^\mu$ | 0.08 | 0.59 | 0.26 | 0.062 | $D_S^\mu = 1.05$ |
| $\mu$       | $B_{\mu}^\mu$ | 1.97 | 6.05 | 0.91 | 1.48 | $\|\mu\|_G = 11.44$ |

5 Variance Decomposition

Regarding existence, it suffices to assume that $\mathcal{M} \subseteq \Psi[g]$. Then, variance-based sensitivity indices are defined for each component measure in $\mathcal{M}$. With regard to uniqueness, the number of variance decompositions coincides with the cardinality of $\mathcal{M}$.

Example 6 (Example 1 continued) Rows three to seven in Table 1 show the variance decompositions of the Ishigami function with parameters $a = 7.0$ and $b = 0.1$ under $\mu_1$, $\mu_2$, and $\mu_3$, respectively. The model output variance is highest under $\mu_1$. Also, under this measure the interaction term $V_{1,3}^\mu$ is higher than under $\mu_3$ and $\mu_2$.

We consider now the case in which the analyst posits a prior $P_\mu$ over the component measures in $\mathcal{M}$. The following holds.

Proposition 7 Given $(\mathcal{M}, \mathcal{F}(\mathcal{M}), P_\mu)$, $g \in \bigcup_{m \in \mathcal{M}} \mathcal{L}^2(\mathcal{X}, \mathcal{B}(\mathcal{X}), \mu^m)$, let $\|G\|$ be the overall variance of $G$ due to uncertainty in $\mathcal{X}$ and $P_\mu$. We have

$$\|G\| = \sum_{z \in 2^\mathcal{Z}, z \neq \emptyset} B_z + \|\mu\|_G,$$

where

$$B_z = E_{P_\mu}[V^\mu_z] = \sum_{m=1}^m p_m V^\mu_z$$

is the weighted average of variance-based sensitivity indices of order $z$.

Proposition 7 shows that, under a mixture of distributions, the variance of $G$ is decomposed into two summands. The first term is the weighted average of the variance decompositions of $G$ under the component measures in $\mathcal{M}$ — structural term, henceforth. The second summand, $\|\mu\|_G$, is the residual portion of the model output variance associated with the variation of the expected value of $G$ across the component measures variability-of-the-mean term, henceforth. Thus, the mixture of ANOVA decompositions would explain the model output variance completely only if there is no variability in the expected value of the model output across the measures in $\mathcal{M}$.

Example 7 (Example 1 continued) For the Ishigami function with the distributions assigned in Example 2 we register $\|\mu\|_G = 11.44$, $\|\mu\|_G = 1.03$, and $\sum_{z \in 2^\mathcal{Z}, z \neq \emptyset} B_z = 10.41$. Thus, the structural term explains about 90% of the model output variance. The variability-of-the-mean term accounts for the residual 10% variation.

5.1 Dimension distribution

The results of the previous section show that, posited $\mathcal{M}$, Owen’s dimension distribution becomes conditional on $\mu^m$. We can write

$$V^\mu_m = \text{Pr}(T_{\mu^m} = z), \ m \in \mathcal{M}.$$
number of dimension distributions equals the cardinality of $\mathcal{M}$. In the without-prior path, the analyst might then inspect the variability of the mean effective dimension as the measures vary in $\mathcal{M}$ to obtain an indication about how interactions vary depending on the assigned distribution.

In the presence of a prior, the dimension distribution regains uniqueness. In fact, by the total probability theorem, we have:

$$
\Pr(T_\mu = z) = \sum_{m=1}^Q p_m \Pr(T_\mu^m = z) = \sum_{m=1}^Q p_m \frac{V^m}{V_\mu[G]}.
$$

(39)

$\Pr(T_\mu = z)$ is now the mixture of the dimension distributions obtained under each measure $\mu^m$. We then have the following result.

**Proposition 8** Under the assumptions of Proposition 7, the mean effective dimensions in the superimposition and truncation sense are unique and equal to $D^S_{\mu} = \mathbb{E}_{P_\mu}[D^S]$ and $D^T_{\mu} = \mathbb{E}_{P_\mu}[D^T]$.

(40)

Equation (40) suggests that the mean effective dimensions in the superimposition and truncation senses are now the mixtures of the conditional dimensions obtained under each measure $\mu$.

**Example 8** (Example 3 continued) Referring again to Table 1, rows nine and ten display the unconditional dimension distribution $\Pr(T_\mu = z)$, for the Ishigami function, and the corresponding unconditional mean effective dimension, which equals $D^S_{\mu} = 1.12$. Rows four, six and eight report the dimension distributions under each measure: They equal $D^1_{\mu} = 1.24$, $D^2_{\mu} = 1.06$ and $D^3_{\mu} = 1.05$ under $\mu^1$, $\mu^2$ and $\mu^3$, respectively. These results indicate that there is variability in the intensity of interaction effects, which are largest under the first measure, and are minimal under the third measure. Therefore, an analyst must place attention as to what is the measure under which the sensitivity analysis is performed when inferring insights about the strength of interaction effects.

### 5.2 Implications for Inference: Robust Sensitivity Analysis Settings

As recommended by best practice, inference using global sensitivity analysis needs to be framed within the so-called sensitivity analysis settings [72]. These settings have been formulated under the unique distribution assumption. We then consider the impact in the formulation of sensitivity settings consequent to the relaxation of such assumption. To fix ideas, consider the factor prioritization setting as defined in [74, p. 705] We are asked to bet on the factor that, if determined (i.e., fixed to its true value), would lead to the greatest reduction in the variance of $G$. Following [74], the appropriate sensitivity measures for factor prioritization are the first order sensitivity indices. Here, if the analyst posits $\mathcal{M}$ without specifying a prior, we have a multiplicity of sensitivity indices. If robust insights are sought, then we are making inference in the following extended setting: We are asked to bet on the model input that, if fixed to its true value, would lead to the greatest expected reduction in the variance of $G$ under all measures $\mu^m$ in $\mathcal{M}$. The operationalization is straightforward. Let us write

$$
\bar{S}_i = \sup_{\mu^m \in \mathcal{M}} S^m_i \quad \text{and} \quad \underline{S}_i = \inf_{\mu^m \in \mathcal{M}} S^m_i.
$$

(41)

The indices $\bar{S}_i$ and $\underline{S}_i$ are the extrema of the first order variance-based sensitivity indices across the distributions in $\mathcal{M}$. Then, we need to look for the model inputs that satisfy:

$$
\bar{S}_i > \underline{S}_j, \text{ for all } j \neq i, \ j = 1, 2, \ldots, n.
$$

(42)

That is, in the robust factor prioritization setting, a model input is the most important, if the inferior of the values of its first order variance-based sensitivity indices is greater than the superior of the first order sensitivity indices of any other model input. If one or more model inputs satisfy the search, then they are robustly the most important model inputs based on
variance reduction. The search can be repeated for the second most important model input, etc. If the search is satisfied for all ranks, we say that the entire ranking is robust.

If the analyst assigns a prior, she(he) might be considering to use the average of the sensitivity indices over the measures in $\mathcal{M}$. Such average equals $B_i$, i.e., the mixture of the first order sensitivity indices. These indices, because they are an average, have the advantage of synthesizing the variance-based indices $V_{\mu}$. However, they relate only to the contribution of a model input to the structural term in (37). If the mean variability term is preponderant, inference based on the sole structural term might not be exhaustive.

**Example 9** For the Ishigami function with the distributions assigned in Example 7, $X_2$ and $X_3$ are, respectively, the most important and least important model inputs in a robust sense. In fact, the values in Table 1 show that the conditions in (42) is satisfied. Consequently, $X_2$ and $X_3$ are also the most and least important model inputs if the average sensitivity indices are taken as sensitivity measures. This coincidence could be expected in this case, as the structural variability term accounts for 90\% of the model output variability.

Concerning trend identification, Proposition 6 suggests the following. If the model is monotonic, then we obtain a monotonic trend under any measure $\mu_m \in \mathcal{M}$ for the first order effects. Then, consider that $\mu^m$ is the measure in use. If we register a non-monotonic trend, the model is not monotonic and the indication holds for any other measure $\mu^m' \in \mathcal{M}$. Conversely, if under $\mu_m$ we register a monotonic trend of the first order effects, we cannot conclude that the model is monotonic.

Concerning interaction quantification, we can define the inferior and superior mean effective dimensions in the superimposition and truncation senses, respectively as

$$D_S = \inf \mu \sum_{|z| > 0} V_{\mu} : |z| \text{ and } D_S = \sup \mu \sum_{|z| > 0} V_{\mu} : |z|$$

and

$$D_T = \inf \mu \sum_{|z| > 0} V_{\mu} \max\{j : j \in z\} \text{ and } D_T = \sup \mu \sum_{|z| > 0} V_{\mu} \max\{j : j \in z\}$$

If a prior is set, we can consider the unconditional dimension distribution and the unconditional mean effective dimensions in eq. (40) to obtain indications on the relevance of interactions.

**6 Discussion**

**6.1 Interpretation and Methodological Aspects concerning Aggregation**

In this section, we discuss methodological aspects concerning the use of multiple distributions, the theoretical rationale that supports our two paths, and the aggregation of experts opinion. Concerning the circumstances that motivate the use of multiple distributions, a first case is the situation in which available data do not uniquely identify a best fit from a family of distributions — see [19] among others. Closely related is the case in which a best fitting family is identified, but uncertainty remains about the values of the parameters. A first example is the application of Hu, Cao and Hong [34] (that we use as starting point in our case study), who assign a multivariate normal distribution with uncertain variance to the model inputs. A second example is the situation in which the analyst has elicited model input distributions from more than one expert, and the experts have provided discordant opinions. A third example is illustrated in [48], and is the case in which alternative scientific studies assign different distributions to a given model input. A fourth case is discussed in the works of [6, 4] and most recently [57], where a robustness question is asked directly by the analyst, who wishes to explore the stability of sensitivity analysis results for perturbations in the model input distributions.

Assigning a prior is necessary for two-stage Monte Carlo sampling [19]. The assignment of a prior is a delicate task and has been thoroughly investigated in the literature — see the monograph [9] for a comprehensive review. [19] provides an accurate methodological summary
and discusses advantages and disadvantages of four methods namely, the use of a uniform prior, the use of a non-informative prior \[7\], of a data-driven prior \[8\] and of the moment-matching method \[8\].

Concerning the theoretical interpretation of using or not a prior, we note a recent decision theory result in \[?\]. The starting point is Wald’s observation that the analyst knows only that the probability distribution of \(X\), that is, the probability measure function \(\mu\) is in the space \(M\) \[83, p. 279\]. Wald’s approach leads to the minimax functional as decision criterion. The minimax philosophy corresponds to the robust settings in Section 5.2. However, \[17, p. 975\] shows that, by enriching Savage’s axioms with Wald’s datum, i.e. positing \(M\), one obtains as a decision criterion a two-stage utility functional whose form is identical to the subjective expected utility criterion of a Bayesian decision maker who assigns a prior \(P\) over the possible distributions. Thus, an expected utility decision maker who has posited \(M\) is, indeed, a Bayesian decision maker who averages uncertainty in distribution using the prior \(P\). This leads directly to the mixture we have discussed.

However, some words of caution are needed about the meaning of a mixture distribution, when the distributions come from experts. In fact, aggregating experts’ opinion is a delicate task. Several aggregation methods are available, and their applicability depends also on the assumptions at the basis of the elicitation procedure. Because of the limited space in this work, we refer to the monographs \[20, 52\], to the review articles \[53, 27\], and to the works \[2, 49, 21\] that offer analyses of critical aspects.

From an expert aggregation perspective, the mixture in (21) can be seen as a linear opinion pool. A popular alternative is the logarithmic opinion pool \[27\]. In this case the distribution is found by aggregating opinions through

\[
\mu_{\logpool}(x) = k \prod_{m=1}^{Q} \mu_{m}(x)^{w_{m}}
\]

where \(k\) is a normalizing constant and the weights \(w_{m}\) are positive and sum to unity. Now, as mentioned, in this work we consider a set \(\mathcal{M}\) of product measures. We can then write

\[
\mu_{\logpool}(x) = k_{n} \prod_{i=1}^{n} \prod_{m=1}^{Q} \mu_{i,m}(x_{i})^{w_{m}}.
\]

Then, if we let \(\mu_{\logpool,i}(x_{i}) = k_{i} \prod_{m=1}^{Q} \mu_{i,m}(x_{i})^{w_{m}}\), we obtain

\[
\mu_{\logpool}(x) = \prod_{i=1}^{n} k_{i} \prod_{m=1}^{Q} \mu_{i,m}^{\logpool}(x_{i}).
\]

Thus, if an analyst aggregates the distributions in \(\mathcal{M}\) using a logarithmic pool, the multiple distribution case is absorbed back into a unique distribution case. The unique distribution is now a product of suitably defined marginals and the properties of the classical ANOVA expansion remain unaltered in this case. That is, uncertainty in distribution impacts the model inputs marginal distributions, but not the classical functional ANOVA expansion. With a similar procedure one can analyze the joint distribution resulting from other aggregation methods and can assess the impact on the functional ANOVA expansion.

6.2 Relationships with the Generalized Functional ANOVA Expansion

We take a step back and consider the unique distribution assumption for a moment. The distribution is \(\mu\) as in Section 2. As we have seen, independence plays an important role in the classical functional ANOVA expansion in \[3\]. The works \[33, 18, 40, 63\] show that we can still recover an expansion of the form of \(2\) without imposing any assumption on \(\mu(x)\). In particular, Rahman considers the following weak annihilating conditions \[63\]

\[
\int_{x_{i}} g_{z}(x_{z}) f_{i}(x_{i}) dx_{i} = 0 \quad \text{for } i \neq z \neq \emptyset,
\]

where \(f_{i}(x_{i})\) is the density of \(x_{i}\), and shows that they lead to the generalized functional ANOVA expansion

\[
g(x) = \sum_{z \in 2^{R}} g_{z,R}(x_{z}).
\]

Here the subscript \(R\) denotes the fact that we are dealing with a generalized component function. Also, \[63\] shows that the generalized component functions remain hierarchically or-
The determination of the generalized component functions is now obtained through a system of coupled equations. To illustrate, for a three-variate function $g(x) = g(x_1, x_2, x_3)$, the equation of the main effect function $g_{1;R}(x_1)$ is [63] p. 678

$$g_{1;R}(x_1) = \int_{x_{2;3}} g(x) d\mu_{x_2, x_3}(x_2, x_3) - g_{0;R} - \int_{x_2} g_{1;2,R}(x_1, x_2) d\mu(x_2) + \int_{x_2} g_{1;3,R}(x_1, x_3) d\mu(x_3) - \int_{x_2, x_3} g_{1;2,3,R}(x_1, x_2, x_3) d\mu_{x_2, x_3}(x_2, x_3).$$

(48)

The expression in (48) involves all the effect functions in the decomposition that contain model input $X_1$. Thus, as opposed to the independence case, the functional ANOVA terms cannot be determined recursively. However, a series of recent works [40, 41, 63] present methodologies for obtaining the generalized ANOVA terms bypassing the coupling problem. In particular, the terms of the decomposed functional ANOVA expansion can be obtained following the procedure in [63] by selecting a basis made of orthonormal polynomials with respect to the mixture measure $\mu_X(x)$.

These works also extend variance-based sensitivity indices for dependent inputs. In particular, [63] shows that it is possible to decompose the variance of $G$ as

$$\mathbb{V}[G] = \sum_{u \in 2^Z \setminus \emptyset} \mathbb{E}_{\mu}[g_{u;R}(X_u)^2] + \sum_{u,v \in 2^Z \setminus \emptyset \atop u \subsetneq v} \mathbb{E}_{\mu}[g_{u;R}(X_u)g_{v;R}(X_v)],$$

(49)

and correspondingly define pairs of variance-based sensitivity indices

$$S^V_u = \mathbb{V}[G]^{-1}\mathbb{E}_{\mu}[g_{u;R}(X_u)^2]$$

(50)

and

$$S^C_u = \mathbb{V}[G]^{-1} \sum_{u,v \in 2^Z \setminus \emptyset \atop u \subsetneq v \subseteq \mathbb{Z}} \mathbb{E}_{\mu}[g_{u;R}(X_u)g_{v;R}(X_v)],$$

(51)

where the first index $S^V_u$ refers to a variance contribution, the second to a covariance contribution $S^C_u$ generated by the presence of correlations. These results can be related to our work. In the with-prior path, in fact, the analyst posits a set of measures $\mathcal{M}$ and assigns a prior $P_\mu$ obtaining a joint model input distribution $\mu_X(x)$, which, as we have seen, is not a product measure. We then have the following identities:

$$\sum_{u \in 2^Z \setminus \emptyset} g^P_u(x_u) = \sum_{u \in 2^Z} g_{u;R}(X_u),$$

(52)

and

$$\sum_{u \in 2^Z \setminus \emptyset} B_u + \mathbb{V}_{P_\mu}[\mathbb{E}_{\mu}[G]] = \sum_{u \in 2^Z \setminus \emptyset} \mathbb{E}_{\mu}[g_{u;R}(X_u)^2] + \sum_{u,v \in 2^Z \setminus \emptyset \atop u \subsetneq v \subseteq \mathbb{Z}} \mathbb{E}_{\mu}[g_{u;R}(X_u)g_{v;R}(X_v)].$$

(53)

Equation (52) relates the mixture functional ANOVA expansion in [4] (left hand side) and the generalized decomposition with respect to the mixture distribution $\mu_X(x)$. Equation (53) relates the decomposition of the model output variance across the measures in $\mathcal{M}$ (left hand side) to the decomposition over the joint mixture distribution $\mu_{\mu_X}(x)$ (right hand side).

Regarding the simultaneous relaxation of the independence and uniqueness assumptions, we hint here at some possible results, which, however, need to be formally addressed in future research. First, if we relax the independence assumption, the decision maker posits a set $\mathcal{M}$ consisting of joint distributions, in which $\mu_{\mu_X}$ is not necessarily a product measure. The generalized functional ANOVA expansion in [17] becomes the relevant expansion. In the without-prior path, the analyst is then dealing with a multiplicity of generalized functional ANOVA decompositions. We argue that the definition of functional ANOVA core and Proposition 3 would still hold, under the condition that two joint measures lead to the same generalized functional ANOVA expansion, and not to the same classical ANOVA expansion.

\footnote{Hierarchical orthogonality is the condition $\mathbb{E}[g_{\mu;R}(X_u)g_{\mu;R}(X_v)] = 0$ whenever $u \subset v$, $u \neq v$.}
Concerning properties such as monotonicity and ultramodularity, we would need to study these properties how the generalized component functions behave with respect to these properties. For variance decomposition in the without-prior path, we would have as many pairs of indices $S^{1}_{k}$ and $S^{2}_{k}$ as many are the measures in $M$. In the with-prior path, we would regain uniqueness of the expansion and of the variance decomposition. However, the disclaimer holds that the investigation of this subject requires more space that can be devoted here and is, we hope, an interesting question of future research.

7 Numerical Implications and An Application

7.1 Estimation: Investigation of the Computational Cost

Uncertainty quantification in the presence of a prior $P_{m}$ is, conceptually, carried out following a two-stage sampling strategy [29]. First, a distribution $\mu^{m}$ is drawn from $M$ according to $P_{m}$ and, subsequently, a sample of values of $X$ is drawn from $\mu^{m}$. Then, conditional on assuming $\mu^{m}$ as a probability measure for the model inputs, the cost of estimating a global sensitivity measure is the same as under any unique measure. We recall that the brute force estimation of all the terms of the functional ANOVA expansion requires a double loop of model evaluations multiplied by the number of terms, leading to a cost $C^{uv} = N^{2}(2^{n} - 1)$, where $N$ is the sample size and $2^{n} - 1$ is the number of terms to be estimated. Then, the overall computational cost $(C^{BF})$ becomes, in principle $C^{BF} = N^{P_{m}}C^{uv} = N^{P_{m}}N^{2}(2^{n} - 1)$, where $N^{P_{m}}$ is the number of sampled distributions. This cost is clearly prohibitive for most computer experiments.

We examine a few strategies to reduce computational burden in the remainder of this section. First, we can lower $C^{uv}$ by profiting of methods developed in previous literature. To illustrate, the design of $\hat{S}$ lowers $C^{uv}$ to $N(n+1)$ to obtain all first and total indices [70, 59]. This cost can be further reduced using a given data design. As mentioned in Section 2 this estimates variance-based sensitivity measures directly on the sample of size $N$ generated for uncertainty quantification by a single-loop Monte Carlo or quasi-Monte Carlo scheme, making the estimation cost independent of the number of model inputs.

A second strategy consists of lowering $N^{P_{m}}$. For instance the re-weighting approach of [8] permits to use a single sample of $N$ model runs. The principle of the approach is similar to importance sampling, and we refer to [8] and [4] for additional details. Thus, combining a re-weighting approach with a given data approach has the potential of reducing the overall cost of the analysis to $N$ model evaluations even in the presence of multiple distributions.

Example 10 To illustrate, we consider estimating the first order sensitivity measures for the Ishigami function. Given a sample of $(X, G)$ generated under $\mu^{1}$ we associate a weight $w = \frac{g}{f}$ with each realization, where $f^{1}$ and $f^{2}$ are the densities corresponding to $\mu^{1}$ and $\mu^{2}$. Mean, conditional means and variance under $\mu^{2}$ can then be computed as weighted local averages or weighted sum of squares from the original sample. The estimated first order sensitivity indices at $N = 10,000$ are $\hat{S}^{1}_{1} = 0.33$, $\hat{S}^{1}_{2} = 0.45$, $\hat{S}^{1}_{3} = 0.00$. Re-weighting this sample leads to the following estimates for the variance-based sensitivity indices under $\mu^{2}$: $\hat{S}^{2}_{1} = 0.11$, $\hat{S}^{2}_{2} = 0.83$, $\hat{S}^{2}_{3} = 0.01$. The numerical values are close to those of Table 3.

The above example refers to the Ishigami model, in which the running time is not an issue. In the case the running time is problematic, then an efficient way to reduce computational burden is represented by fitting the original model through a metamodel. The metamodel can then be used to carry out an analysis under alternative distributions. Here, some provisions need to be taken. For instance, the support assigned by the analyst may change with the measures in $M$ — see Example 1. Then, we may wish to train the metamodel on the distribution with the largest support. To illustrate, suppose in Example 4 we use a sample coming from the third assignment where support is $[0, 1]^{3}$ to fit the metamodel. If we use this metamodel to replace the original model and sample from the second distribution, in some instances we might be evaluating the emulator on values of the inputs falling outside the original training.
Table 2: Distributional Assumptions in Nordhaus (2008) original Uncertainty Quantification; Table 7-1, p. 127, \[50\].

| $\chi_i$ | Model Input Name                                      | Mean     | Std. Deviation |
|---------|-------------------------------------------------------|----------|----------------|
| $\chi_1$ | Growth in total factor productivity                   | 0.0092   | 0.004          |
| $\chi_2$ | Initial sigma growth                                  | 0.007    | 0.002          |
| $\chi_3$ | Climate sensitivity                                   | 3        | 1.11           |
| $\chi_4$ | Damage function exponential factor                   | 0.0028   | 0.0013         |
| $\chi_5$ | Cost of backstop in 2005                              | 1170     | 468            |
| $\chi_6$ | POPASYM                                               | 8600     | 1892           |
| $\chi_7$ | $b_{12}$ in carbon cycle transition matrix           | 0.189    | 0.017          |
| $\chi_8$ | Cumulative fossil fuel extraction                     | 6000     | 1200           |

with little control of the accuracy of the metamodel on these points if deviations from linearity are present. However, this is just a first aspect that appears in the presence of multiple distributions and a full investigation is outside the reach of the present work.

7.2 Application: Sensitivity of the DICE Model with Multiple Distributions

A topical field characterized by scientific ambiguity is climate change \[48\]. Analysts, in fact, are frequently unable to assign a unique distribution to the inputs of integrated assessment models. Then, the question is whether we can still obtain robust insights from sensitivity analysis of integrated assessment models under uncertainty in distribution. Our application is motivated by the results of the very recent and influential investigation of \[28\], where the developers of six of the most widely recognized integrated assessment models perform a thorough and systematic uncertainty analysis of the response of integrated assessment models (IAMs) in climate change. IAMs are sophisticated computer codes that simulate complex phenomena related to climate change evolution. One of the key findings is that parametric uncertainty is more important than uncertainty in model structure \[28\, p. 1\]. These findings show, once again, the need of performing a rigorous sensitivity analysis, especially if the goal is the identification of the key-drivers of uncertainty.

Because our purpose is illustrative, and also for granting reproducibility of our results, we focus on William Nordhaus’ \[50\] Dynamic Integrated Climate-Economy (DICE) model and specifically on the baseline (no controls) case in that model\[1\]. DICE is one of the best known IAMs and has been applied and used as a benchmark in several studies concerning uncertainty quantification in climate change modelling. Aside from the original uncertainty analysis in \[50\], a variance-based sensitivity analyses of DICE is performed by \[13\] and \[12\]. More recently, \[11\] extend the analysis by estimating also the $\delta$-importance measure. DICE has also been used as a test case in robust optimization contexts, in studies such as \[48, 45, 34\]. As Hu et al. underline \[34\], the starting point for an uncertainty analysis of the DICE model is the investigation performed by Nordhaus himself in Chapter 7 of \[50\]. We report the reference distributions in Table 2.

Nordhaus \[50\, p. 126\] remarks: \textit{It should be emphasized that these distributions are indeed judgmental and have been estimated by the author. Other researchers would make, and other studies have made, different assessments of the values of these parameters. Indeed, alternative distributions are used in subsequent studies. For instance, in \[44\] and \[39\] only four uncertain model inputs are considered and the assigned distributions differ from the ones in the original study of \[50\], and in \[44\] a second order distribution over the mean and variances of Table 2. In \[34\], Section 4.3\] the standard deviations of the model inputs are allowed a fifty percent decrease and increase a twenty percent increase. To illustrate a sensitivity analysis in this context, we discretize the variations in the standard deviations and let $\mathcal{M} = \{\mu_1^X(x), \mu_2^X(x), \ldots, \mu_9^X(x), \mu_{10}^X(x), \ldots, \mu_{19}^X(x)\}$, where: 1) $\mu_i^X(x)$ is Nordhaus’s original distribution; 2) $\mu_1^X(x), \ldots, \mu_9^X(x)$ are joint distributions with one of the model input variances shifted to its lower (upper) value, \[\mu_{10}^X(x), \ldots, \mu_{19}^X(x)\]$.
with the remaining fixed at the reference values of Table 2 and 3) \( \mu_{18}^X(x) \) and \( \mu_{19}^X(x) \) are distributions with all model input variances at their lowest and highest values, respectively. For the with-prior path, we assign \( P(\mu_{18}^X) = P(\mu_{19}^X) = \frac{1}{5}, \) and the remaining probabilities equal to \( P(\mu_m^X) = \frac{1}{40} \) for \( m = 2, 3, \ldots, 17. \)

To produce results while taking computation burden under control we proceed as follows. We consider the original distributions of \[50\] and generate a sample of size \( N = 10,000. \) The calculations are performed in the General Algebraic Modeling System (GAMS), a platform for mathematical programming and optimization, in which the DICE model is implemented and evaluated. The 10,000 evaluations take about 12 hours on a PC with 8GB RAM, dual core. Then, for the analysis of the remaining 18 distributions, we train an emulator through Kriging to substitute the original model. The emulator fit registers an \( R^2 \) coefficient of 0.97.

As a model output of interest we consider the change in atmospheric temperature in year 2100. Figure 1 displays the values of the first order sensitivity measures across the 19 scenarios. b Because we are in the without-prior path, we adopt the robust sensitivity setting of Section 5.2.

Figure 1: Boxplots of the normalized first and total order variance based sensitivity measures across the 19 assigned distributions.

The sensitivity measures in a robust factor prioritization setting are the first order sensitivity indices. We consider then the left graph in Figure 1. We observe that \( X_3, \) climate sensitivity, is robustly the most important, because (42) is satisfied for this model input. As for the runner up, model input \( X_5 \) is ranked second in 16 out of the 19 distribution assignments, and ranks 3\(^{rd}\) in two and 4\(^{th}\) in one. Model input \( X_6 \) ranks second in 3 out of 19 measures in \( M \) and ranks 3\(^{rd}\) otherwise. To recover robust rankings, we need to go to the least important model inputs, \( X_1, X_7 \) and \( X_8, \) which rank 7\(^{th}\), 6\(^{th}\) and 8\(^{th}\) under all measures in \( M. \)

Concerning interaction quantification, at Nordhaus’ original distribution assignment, the sum of first order indices is estimated at 0.93, signalling a low impact of interactions. Over the additional eighteen measures, the estimate of the sum of the first order sensitivity measures ranges from a minimum of 0.92 (last measure) to a maximum of 0.96 (second last measure). Note that these two measures are the ones where the model input variances are at their maxima and their minima, respectively. Using a subroutine based on regression with harmonic cosine functions, we calculated the second order sensitivity indices. We register a sum of the first and second order indices close to unity, indicating that higher order interaction effects are negligible. We can then approximately compute the dimension distributions over the nineteen scenarios and the corresponding mean effective dimension in the superimposition sense. In the original Nordhaus assignment, the mean effective dimension is estimated at 1.09. Over the additional 18 scenarios, we register \( D_S = 1.03 \) and \( D_S = 1.13. \) Again, these values confirm the low impact of interactions.

Regarding trend identification, the plots of the first order terms (Figure 2) show that the model is not monotonic. In particular, the expected behavior of \( G \) is decreasing in \( X_4 \) and \( X_7, \) while increasing in the remaining model inputs. The graphs also confirm the high sensitivity of the model output on changes in \( X_3, \) and the low sensitivity on \( X_1, X_7 \) and \( X_8. \) We observe
that temperature change in 2100 is increasing with respect to the climate sensitivity, the most important parameter. This result is in accordance with intuition, because the higher climate sensitivity the higher the expected increase in temperature.

In the with-prior path, one registers $\sqrt{\text{Var}(G)^{-1} \text{Var}_p [\text{E}_{\mu_m}[G]] \approx 3.5 \cdot 10^{-4}$, signaling that the fraction of $\sqrt{\text{Var}(G)}$ explained by the variation in the mean is about 1.8%. Because this ratio is small, we can consider the averages of the first order sensitivity indices, which is displayed in Figure 2. They also indicate climate sensitivity as the most important parameter, followed by the cost of backstop in 2005. Regarding interaction quantification, the unconditional dimension distribution in (39) is estimated at about 1.08. This result signals a low impact of interactions, in agreement with the without-prior case. Regarding trend identification, the first order mixture effects are displayed in Figure 2 as dotted lines. The behavior of these effects is in agreement with the indications obtained in the without-prior case.

8 Conclusions

This work has provided a first systematic study of the classical functional ANOVA expansion when the unique distribution assumption is relaxed. Such relaxation impacts properties of the expansion such as existence, uniqueness, orthogonality, ultramodularity and monotonicity. We have addressed these properties considering two main paths, depending on whether the analyst is willing to assign a prior. We have seen that, in the without-prior path, the analyst is dealing with a multiplicity of functional ANOVA expansions and, consequently, of variance-based sensitivity measures. In this context, we have introduced robust sensitivity settings. In the with-prior path, the analyst regains uniqueness and the mixture of functional ANOVA expansions equals the original mapping. We have searched for conditions that allow the analyst to proceed as if the distribution was unique. We have discussed how insights concerning monotonicity are impacted by the assignment of a set $\mathcal{M}$ of plausible distributions. Moreover, if the analyst aggregates the distributions in $\mathcal{M}$ using a logarithmic opinion pool, then she(he) obtains a unique product distribution that allows her(him) to proceed as if the distribution was unique. Our case study applies the findings to a well known climate model, DICE, under uncertainty in distribution, drawing from previous studies performed on the same model. Results show that when the temperature change in 2100 is the variable of interest, climate sensitivity is consistently the most important model input over the alternative distributions. Because this model input has been indicated by [48] among the traditional uncertainties in climate modelling, this result confirms the im-

Figure 2: Plots of the first order terms of the functional ANOVA expansion of the DICE model over the 19 distributions. The plots have been obtained using the SSANOVA.m code of [66].
portance of using a robust approach when making inferences on temperature changes using the DICE model.

Acknowledgments

The authors wish to thank the Editor, the Associate Editor and the anonymous reviewers for the very perceptive comments that have greatly helped us in ameliorating the manuscript, clarifying is contributions and limitations. We also wish to thank Steven Chick for the enlightening discussion during the INFORMS 2012 conference in Phoenix. The authors wish also to thank Jeremy Oakley for several constructive comments on this work.

9 Appendix A: Proofs

Proof 1 (Proof of Proposition 3) Consider the relation \( \mu' \leq \mu'' \) defined by whether \( \mu' \) and \( \mu'' \) belong to the same core. This is an equivalence relation. Passing over to the associated equivalence classes yields a partition of \( \Psi[\mu] \).

Proof 2 (Calculations for Example 2) Under model input independence, \( g^{\mu}_0 = \sum_{u \in 2^X} \prod_{i \in u} E[t_i(X_i)] \) and \( g^{\mu'}_0 = \sum_{u \in 2^X} \prod_{i \in u} E[t_i(X'_i)] \) which coincide when all \( E[t_i(X_i)] \) are equal to \( E[t_i(X'_i)] \). We consider an induction over \( |z| \). Assuming \( g^\nu_0 = g^{\nu'}_0 \) for all \( \nu \subset z, \nu \neq z \), \( E[t_i(X_i)] = E[t_i(X'_i)] \) for all \( i \) implies \( g^z_0 = g^{z'}_0 \), because

\[
\int_{X \sim \mu} g(x) d\mu(x) = \sum_z \int_{X \sim \mu} \prod_{i \in z} t_i(x_i) d\mu(x_{\sim z}) = \sum_z \prod_{i \in z} t_i(x_i) \prod_{i \notin z} E[t_i(X_i)]
\]

is equal to \( \int_{X \sim \mu'} g(x) d\mu'(x_{\sim z}) \).

Proof 3 (Proof of Proposition 4) By Proposition 1 for any measure \( \mu \in \Psi[\mu] \), one can write the function \( g \) as \( g(x) = \sum_{z \in 2^X} g^\mu_z(x_z) \). Then, given \( (M,F(M),P_\nu) \), let us take the expectation of both sides:

\[
E_{P_\nu}[g(x)] = E_{P_\nu}\left[ \sum_{z \in 2^X} g^\mu_z(x_z) \right] = \sum_{m=1}^Q p_m \sum_{z \in 2^X} g^{\mu_m}_z(x_z).
\]

Because \( g(x) \) is independent of \( \mu \), we obtain \( E_{P_\nu}[g(x)] = g(x) \). Note that this equality holds under any measure \( P_\nu \). For the right hand side, by the linearity of the expectation operator, we have:

\[
E_{P_\nu}\left[ \sum_{z \in 2^X} g^{\mu_m}_z(x_z) \right] = \sum_{z \in 2^X} E_{P_\nu}[g^{\mu_m}_z(x_z)].
\]

Then, by definition \( E_{P_\nu}[g^{\mu_m}_z(x_z)] = g^{\mu_\nu}_z(x_z) \).

Proof 4 (Proof of Proposition 5) We start with the expected value of \( G \). We have

\[
E_{g\mu}[G] = \int g d\mu = \int \sum_{m=1}^Q p_m d\mu^m = \sum_{m=1}^Q p_m \int g d\mu^m = \sum_{m=1}^Q p_m g^{\mu_m}_0
\]

The equality follows by the first equality in (24). Concerning the generic effect function, it suffices to prove the identity for conditional expectations. We have

\[
w^{\mu}_F(x_z) = \int_X (g(x,z,x_{\sim z})) d\mu(x_{\sim z}) = \int g(x,z,x_{\sim z}) \sum_{m=1}^Q p_m d\mu^m(x_{\sim z}) = \sum_{m=1}^Q p_m \int g(x,z,x_{\sim z}) d\mu^m(x_{\sim z}) = \sum_{m=1}^Q p_m w^{\mu_m}_F(x_z) = E_{P_\nu}[w^{\mu_m}_F(x_z)] = w^{\mu}_F(x_z)
\]
Proof 5 (Proof of Proposition 6) Item 1. By Lemma 1, if $g$ is non-decreasing, then $w^{\mu}(x_{i})$ is non-decreasing for any measure $\mu$. Equation 2 shows that a generalized non-orthogonalized effect function is the linear combination of $w^{\mu}(x_{i})$ with positive weights. Therefore $\int w^{\mu}(x_{i})dP(\mu)$ or $\sum_{m=1}^{Q}p_{m}w^{\mu}(x_{i})$ is, then, non-decreasing in $x_{i}$. $w^{\mu}(x_{i})$ is, then, non-decreasing. Item 2 follows from the same reasoning as for Item 1.

Item 3 is proven as follows. By assumption, because $p_{m} \geq 0$, (or $dP(\mu) \geq 0$) for a generic $\mu^{m}$ it is $p_{m}\Delta w^{\mu}_{\nu} \geq p_{m}\sum_{v \subset z} \Delta g^{\nu}_{v}$, where $v \subset z$ denotes true subsets, the case $v = z$ is excluded. Then, the following is true:

\[
\sum_{m=1}^{Q}p_{m}\Delta w^{\mu}_{\nu} \geq \sum_{m=1}^{Q}p_{m}\Delta g^{\nu}_{v} = \sum_{v \subset z} \sum_{m=1}^{Q}p_{m}\Delta g^{\nu}_{v} = \sum_{v \subset z} \Delta g^{\nu}_{v}
\]  

(57)

Noting that the left-hand side is $\Delta w^{\mu}_{\nu}$, we have $\Delta w^{\mu}_{\nu} \geq \sum_{v \subset z} \Delta g^{\nu}_{v}$.

Proof 6 (Proof of Proposition 7) The following holds by the law of total variance:

\[
\mathbb{V}[G] = E_{P_{\mu}}[\mathbb{V}[G|\mu^{m}]] + \mathbb{E}_{P_{\mu}}[E[G|\mu^{m}]]
\]  

(58)

Under the generic input distribution $\mu^{m}$ (53) applies, so that $\mathbb{V}[G] = \sum_{z \in 2^{\mathbb{Z}}, \neq \emptyset} \mathbb{V}^{\mu^{m}}(z)$, from which we obtain

\[
\mathbb{V}[G] = E_{P_{\mu}}[\sum_{z \in 2^{\mathbb{Z}}, \neq \emptyset} \mathbb{V}^{\mu^{m}}(z)] + \mathbb{E}_{P_{\mu}}[E[G|\mu^{m}]] = \sum_{z \in 2^{\mathbb{Z}}, \neq \emptyset} B_{z} + \mathbb{E}_{P_{\mu}}[E[G|\mu^{m}]]
\]  

(59)

which holds by the linearity of the summation and expectation operators.

Proof 7 (Proof of Corollary 8) We start with the first equality in (10). By definition we have

\[
D_{S} = \sum_{|z| > 0} |z| \text{Pr}(T_{\mu} = z) = \sum_{|z| > 0} |z| E_{P_{\mu}}[\text{Pr}(T_{\mu} = z|\mu = \mu^{*})] = E_{P_{\mu}}[\sum_{|z| > 0} |z| \text{Pr}(T_{\mu} = z|\mu = \mu^{*})] = E_{P_{\mu}}[D_{S}^{\mu}].
\]

For the second equality in (10), we proceed in a similar way, obtaining:

\[
D_{T} = \max_{|z| > 0} \sum_{j \in z} \text{Pr}(T_{\mu} = z) = \max_{|z| > 0} \sum_{j \in z} E_{P_{\mu}}[\text{Pr}(T_{\mu} = z|\mu = \mu^{*})] = E_{P_{\mu}}[\max_{|z| > 0} \sum_{j \in z} \text{Pr}(T_{\mu} = z|\mu = \mu^{*})] = E_{P_{\mu}}[D_{T}^{\mu}].
\]

10 Appendix B: Mixture Functional ANOVA and Ultramodularity

As anticipated in the main text, we discuss here the relationship between the mixture of functional ANOVA expansion and ultramodularity.

Definition 3 (80) $g : \mathcal{X} \rightarrow \mathbb{R}$ is ultramodular, if

\[
g(x^{1} + \Delta x) - g(x^{1}) \leq g(x^{2} + \Delta x) - g(x^{2})
\]  

(60)

for all $x^{1}, x^{2} \in \mathcal{X}$, $\Delta x \geq 0$ with $x^{1} \leq x^{2}$ and $x^{1} + \Delta x^{1}, x^{2} + \Delta x \in \mathcal{X}$. If the inequality in (60) is reversed, we say that $g(\cdot)$ is neg-ultramodular.

Relevant properties of ultramodular functions are discussed in (80) and (114). In (80), the question of whether ultramodularity is preserved within a functional ANOVA expansion is addressed. We summarize the main results in the following lemma.

Lemma 2 If $g$ is ultramodular, then

1) all non-orthogonalized effects $w^{\mu}_{\nu}(x_{i})$ in its functional ANOVA expansion are ultramodular
2) all (orthogonalized) first order effects in its ANOVA expansion are ultramodular.

3) Given $\Delta x \geq 0$, if

\[
\Delta w^\mu_{\sigma}(y) - \Delta w^\mu_{\sigma}(x) \geq \sum_{\nu \in \mathcal{C}} \Delta g^\nu_{\sigma}(y) - \sum_{\nu \in \mathcal{C}} \Delta g^\nu_{\sigma}(x)
\]

(61)

where

\[
\Delta w^\mu_{\sigma}(y) = w^\mu_{\sigma}(y_{\sigma} + \Delta x_{\sigma}) - w^\mu_{\sigma}(y_{\sigma}) \quad \text{and} \quad \Delta w^\mu_{\sigma}(x) = w^\mu_{\sigma}(x_{\sigma} + \Delta x_{\sigma}) - w^\mu_{\sigma}(x_{\sigma})
\]

(62)

\[
\Delta g^\nu_{\sigma}(y) = g^\nu_{\sigma}(y_{\sigma} + \Delta x_{\sigma}) - g^\nu_{\sigma}(y_{\sigma}) \quad \text{and} \quad \Delta g^\nu_{\sigma}(x) = g^\nu_{\sigma}(x_{\sigma} + \Delta x_{\sigma}) - g^\nu_{\sigma}(x_{\sigma})
\]

then all effects in the functional ANOVA expansion of $g$ under measure $\mu$ are ultramodular.

The next result states that the mixed functional ANOVA expansion of $g$ preserves results obtained with a unique input distribution when ultramodularity is concerned.

**Proposition 9** Given a prior $(\mathcal{M}, F(\mathcal{M}), P_{\mu})$ and $g \in \bigcap_{w \in \mathbb{X}; \mathcal{M}} L^1(\mathcal{X}; \mathcal{B}(\mathcal{X}), \mu^m)$. If $g$ is ultramodular on $\mathcal{X}$ then the following holds for its mixture functional ANOVA expansion:

1) the non-orthogonalized effects of any order, $w_{\sigma,\nu}^{P_{\mu}}(x_{\sigma})$, are ultramodular;
2) all orthogonalized first order effects are ultramodular;
3) given $\Delta x > 0$, if, for all $\mu \in \mathcal{M}$ eqs. (61) and (62) hold, then all effect functions in (44) are ultramodular.

**Proof (Proof of Proposition 9)**

Item 1. By item 1 of Lemma 8 the ultramodularity of $g$ ensures that $w_{\sigma,\nu}^{P_{\mu}}(x_{\sigma})$ is ultramodular for any given probability measure $\mu$. Then, $w_{\sigma,\nu}^{P_{\mu}}(x_{\sigma})$ is the convex combination of ultramodular functions, which is ultramodular by Proposition 4.1 in [22], p. 317.

Item 2. By item 2 of Lemma 8 if $g$ is ultramodular, then any $g_{\sigma,\nu}^{P_{\mu}}(x_{\sigma})$ is ultramodular given $\mu$. Hence, because $g_{\sigma,\nu}^{P_{\mu}}(x_{\sigma})$ is a convex combination of ultramodular functions, it is ultramodular as well by Proposition 4.1 in [22], p. 317.

Item 3 is proven as follows. By the assumptions of item 3, for a generic $\mu$ it is:

\[
\Delta w^\mu_{\nu}(y) - \Delta w^\mu_{\nu}(x) \geq \sum_{\nu \in \mathcal{C}} \Delta g^\nu_{\sigma}(y) - \sum_{\nu \in \mathcal{C}} \Delta g^\nu_{\sigma}(x)
\]

(63)

Taking the expectation of both sides, by the linearity of the involved operators,

\[
\mathbb{E}_{P_{\mu}}[\Delta w^\mu_{\nu}(y) - \Delta w^\mu_{\nu}(x)] \geq \mathbb{E}_{P_{\mu}}[\sum_{\nu \in \mathcal{C}} \Delta g^\nu_{\sigma}(y) - \sum_{\nu \in \mathcal{C}} \Delta g^\nu_{\sigma}(x)]
\]

(64)

we obtain

\[
\Delta w_{\sigma,\nu}^{P_{\mu}}(y) - \Delta w_{\sigma,\nu}^{P_{\mu}}(x) \geq \sum_{\nu \in \mathcal{C}} \Delta g_{\sigma,\nu}^{P_{\mu}}(y) - \sum_{\nu \in \mathcal{C}} \Delta g_{\sigma,\nu}^{P_{\mu}}(x)
\]

(65)
