Abstract. The cosmic abundance of a long-lived charged particle such as a stau is tightly constrained by catalyzed big bang nucleosynthesis. One of the ways to evade the constraints is to dilute these particles with a huge entropy production. We evaluate the dilution factor in a case where non-relativistic matter dominates the energy density of the universe and decays with large entropy production. We find that large Q balls can fulfill this role; they are naturally produced in the gauge-mediated supersymmetry breaking scenario.

Keywords: dark matter, big bang nucleosynthesis, cosmology of theories beyond the SM, physics of the early universe
1. Introduction

Gauge-mediated supersymmetry (SUSY) breaking (GMSB) [1] is appealing since the problems associated with the dangerous flavor-changing processes and CP violations are elegantly solved. In this scenario, the gravitino mass $m_{3/2}$ is lighter than the weak scale and therefore the gravitino is most probably the lightest supersymmetric particle (LSP). If the $R$-parity is conserved, the gravitino LSP is absolutely stable and can be a good dark matter (DM) candidate [2]–[7]. In addition, such a scenario with a light gravitino may lead to spectacular collider signatures especially if the next-to-lightest superparticle (NLSP) is an electrically charged particle such as a stau. The stau NLSP has a quite long lifetime, since the decay rate is suppressed by the Planck scale $M_P \simeq 2.4 \times 10^{18}$ GeV.

Such longevity may enable us to measure the Planck scale in collider experiments and therefore to test supergravity [8], if the gravitino mass is $O(10)$ GeV.

However, the existence of such long-lived charged particles can jeopardize the success of big bang nucleosynthesis (BBN). Since the stau decays during or after BBN, the energetic decay products may alter the primordial abundance of the light elements [9,10]. Furthermore, it was recently found that the negatively charged (long-lived) particle can form bound states with nuclei (e.g., $^4\text{He}+\tilde{\tau}^-$), which catalyze the nuclear reactions and substantially change the abundance of the light elements such as $^6\text{Li}$ [11]. Detailed discussion based on the catalyzed BBN (CBBN) leads to a limit on the lifetime of the stau: $\lesssim 10^3$ s, assuming the thermal relic abundance for the stau. Taking the upper bound at face value, we are led to smaller $m_{3/2}$ and/or heavier $m_\tau$, which are challenging from the experimental point of view and on the basis of naturalness.

To alleviate the BBN constraints, several solutions (e.g., $R$-parity violation [12]) have been proposed. Among them, the simplest is assuming that there is late-time entropy production to dilute the stau abundance. According to reference [13], the necessary dilution factor is $\Delta = (300–600) \times (m_\tau/100 \text{ GeV})$ for $m_{3/2} = 10$ GeV, where $m_\tau$ denotes the stau mass. However, successful late-time entropy production is not so easily achieved as one might think. The reason is as follows [14]. For concreteness, we assume that the gravitino is the LSP while the stau is the NLSP, and that a scalar field $X$ with even $R$-parity produces large entropy. Then the scalar mass $m_X$ must be lighter than $m_\tau$, ...
since the supersymmetric partners of the standard-model (SM) particles, if kinematically allowed, are generically produced from the decay of $X$ [15, 16]. In addition, since $m_X$ is lighter than the stau mass, $X$ must be more strongly coupled to the SM particles than the gravitational interactions$^3$, in order to decay before BBN. On the other hand, the fermionic partner of $X$ must be heavier than $m_{\tilde{\tau}}$, because we have assumed that the stau is NLSP. Therefore the mass spectrum must satisfy $m_X < m_{\tilde{\tau}} < m_{\tilde{X}}$, where $m_{\tilde{X}}$ is the mass of the fermionic partner of $X$. To realize such a spectrum, however, one needs a partial cancellation between the SUSY mass and the soft SUSY breaking mass. Thus, it is difficult, if not impossible, to naturally induce a late-time entropy production in the set-up with the gravitino LSP and the stau NLSP.

In this paper, we show that the successful entropy production can be achieved by the decay of the Q ball in the minimal supersymmetric SM (MSSM). In our scenario, a large charge $Q$ naturally makes the effective mass smaller than $m_{\tilde{\tau}}$ and it also explains the longevity of the Q ball. Since the fermionic partners are nothing but the SM particles, there is no constraint on the fermion mass. In addition, the right amount of the baryon asymmetry can be generated by the Affleck–Dine (AD) mechanism [17, 18].

In the next section, we provide a brief review on the Q balls in GMSB. We estimate the dilution factor in both cases when the Q ball dominates the universe after and before the freeze-out of the stau in section 3. In section 4, we show that the Q-ball decay can dilute the stau by the desired amount. In section 5 we give our conclusion and discussion.

2. Q ball in GMSB

A Q ball is a non-topological soliton of a complex scalar field $\Phi$ given by the minimum energy configuration with a fixed $U(1)$ charge $Q$ [19]. One of the conditions for the Q balls to be formed is that the scalar potential with a $U(1)$ symmetry is shallower than the quadratic potential at large field value. The Q balls are known to be formed in association with the scalar dynamics of the MSSM fields, especially in connection with the AD mechanism [17, 18]. In addition, since the Q balls generically have a very long lifetime, they can play important roles in cosmology.

In MSSM, there are many flat directions composed of some combination of squarks, sleptons and Higgs bosons. Along the flat directions, both $F$-term and $D$-term potentials vanish in the exact SUSY limit at a renormalizable level [18, 20]. They are lifted by the soft SUSY breaking effects, non-renormalizable operators, and finite temperature effects. In the AD mechanism, one of the flat directions (denoted by $\Phi$) is assumed to have a large field value during inflation$^4$. After inflation, $\Phi$ starts to oscillate when the Hubble parameter becomes comparable to the mass of $\Phi$. At the same time, $\Phi$ acquires the baryon (and/or lepton) asymmetry, due to non-renormalizable baryon (lepton) number violating operators that are effective only at large field values. The scalar potential of $\Phi$ has an approximate $U(1)$ symmetry corresponding to the baryon and lepton symmetries that are conserved at low energy effective theory, i.e., MSSM. As we will see below, since the scalar potential is shallower than the quadratic potential above the messenger scale in GMSB, $\Phi$

$^3$ This ameliorates a possible gravitino production from the scalar field $X$ [16].

$^4$ Actually, multiple flat directions can have large expectation values simultaneously, but we do not consider this possibility for simplicity.
entrepot production by Q-ball decay for diluting long-lived charged particles

experiences spatial instabilities and deforms into Q balls, where the charge \( Q \) corresponds to the baryon and/or lepton numbers.

As mentioned above, the scalar potential is lifted by the SUSY breaking effects, non-renormalizable operators, and finite temperature effects. In GMSB, the scalar potential above the messenger scale is given by

\[
V(\Phi) \simeq M_F^4 \left( \log \frac{|\Phi|^2}{M_S^2} \right)^2 + c_g m_{3/2}^2 \left( 1 + K \log \frac{|\Phi|^2}{M_B^2} \right) |\Phi|^2 + \frac{\lambda^2 |\Phi|^{2(n-1)}}{M_P^{2(n-3)}}
\]

\[
+ c_T T^4 \log \frac{|\Phi|^2}{T^2} - c_H H^2 |\Phi|^2,
\]

where \( m_{3/2} \) is the gravitino mass, \( M_P \simeq 2.4 \times 10^{18} \) GeV is the reduced Planck scale, and we omit the baryon (lepton) number violating operators here. The first term comes from the GMSB effect above the messenger scale \( M_S \). \( M_F \) and \( M_S \) are related to the \( F \) and \( A \) components of a gauge-singlet chiral multiplet \( S \) in the messenger sector as

\[
M_F^2 = \frac{g^2}{(4\pi)^4} \kappa^2 \langle F_S \rangle^2, \quad M_S = \kappa \langle S \rangle,
\]

respectively, where \( g \) collectively stands for the SM gauge couplings, and \( \kappa \) denotes the Yukawa coupling constant for \( S \) and the messenger fields. In general, \( M_F \) could be in the range \( 10^3 \) GeV \( \lesssim M_F \lesssim 0.1 \sqrt{m_{3/2} M_P} \sim 5 \times 10^8 \) GeV for \( m_{3/2} = 10 \) GeV. The second term of equation (1) comes from the gravity-mediated SUSY breaking, and the coefficient \( c_g \) is of order unity. Here the one-loop correction is included, and \( K \) is negative with \( |K| = 0.1 \)–\( 0.01 \) for most of the flat directions. Since the gravitino mass is relatively small in the gauge mediation, this term is effective for a large field value of \( \Phi \). The third term in the potential is due to a non-renormalizable interaction in the superpotential of the form \( W_{NR} = \lambda \Phi^n / (n M_P^{n-3}) \) with \( n > 3 \), where \( \lambda \) is a coupling constant. The fourth term is a two-loop thermal correction to the potential \([22]\). The coefficient \( c_T \) can be either positive or negative depending on which flat direction we choose \([23]\), and the absolute value is roughly given by \( f_T = O(0.1) \), where we define \( |c_T| = f_T^4 \). The last term is a Hubble-induced mass term, which stems from the quartic coupling in the Kähler potential between the flat direction and the inflaton \([18]\). This term is absent after the reheating of the inflaton. Because of this term, the potential has a minimum at a large field value of \( \Phi \). The \( \Phi \) field is trapped there and it serves as the initial condition for the later dynamics\(^5\). For concreteness, we assume throughout this paper that the minimum is given by the balance between the Hubble-induced mass term and the non-renormalizable operator:

\[
\phi_{\text{min}} \sim \left( \frac{H}{\lambda M_P} \right)^{1/(n-2)} M_P,
\]

where \( \phi \equiv \sqrt{2} |\Phi| \). The flat direction \( \Phi \) traces the minimum until it starts to oscillate.

After inflation, the flat direction starts rotating, experiences spatial instability, and deforms into Q balls \([25]\)–\([29]\). The properties of the Q ball are well known. The charge \( Q \) is determined by the amplitude of the \( \Phi \) field at the onset of the oscillations, \( \phi_{\text{osc}} \). If the

\(^5\) The same effect may be realized by large enough Hubble-induced \( A \) terms \([24]\).
potential at $\phi = \phi_{\text{osc}}$ is dominated by the first or fourth term in equation (1), the charge of the Q ball, which is called gauge-mediation type, is determined as [29]

$$Q = \beta \left( \frac{\phi_{\text{osc}}}{M(T)} \right)^4,$$

where $M(T)$ is defined as

$$M(T) = \begin{cases} M_F & \text{for } M_F > f_T T_{\text{osc}} \\ f_T T_{\text{osc}} & \text{for } f_T T_{\text{osc}} > M_F. \end{cases} \quad (5)$$

The subscript ‘osc’ denotes that the variable should be evaluated at the onset of the oscillation of $\Phi$. The numerical coefficient $\beta$ is given by [27,29]

$$\beta \simeq \begin{cases} 6 \times 10^{-4} \epsilon & \text{for } \epsilon \gtrsim 0.1 \\ 6 \times 10^{-5} & \text{for } \epsilon \lesssim 0.1, \end{cases} \quad (6)$$

where $\epsilon (\geq 1)$ denotes the ratio of the baryon number density to the number density of $\Phi$. The size and mass of the Q ball, and the effective mass of the field inside the Q ball (i.e., the mass per unit charge) are written respectively as [25,29]

$$R_Q \simeq \frac{1}{\sqrt{2M(T)}} Q^{1/4}, \quad M_Q \simeq \frac{4\sqrt{2}\pi}{3} M(T) Q^{3/4}, \quad \omega_Q \simeq \sqrt{2\pi M(T)} Q^{-1/4}. \quad (7)$$

On the other hand, if the potential at $\phi = \phi_{\text{osc}}$ is dominated by the second term in equation (1), the gravity-mediation type of Q ball is formed, whose charge is given by [29,30]

$$Q = \beta' \left( \frac{\phi_{\text{osc}}}{m_{3/2}} \right)^2,$$

where

$$\beta' \simeq \begin{cases} 6 \times 10^{-3} \epsilon & \text{for } \epsilon \gtrsim 0.1 \\ 6 \times 10^{-4} & \text{for } \epsilon \lesssim 0.1. \end{cases} \quad (9)$$

The size and mass of the Q ball, and the effective mass of the field inside the Q ball (i.e., the mass per unit charge) are written respectively as [26,29,30]

$$R_Q \simeq \frac{\sqrt{2}}{|K|^{1/2} m_{3/2}}, \quad M_Q \simeq m_{3/2} Q, \quad \omega_Q \simeq m_{3/2}. \quad (10)$$

The Q ball can decay if the mass per unit charge $\omega_Q$ is larger than the decay products that carry the same charge. For example, if $Q$ is the baryon number, the lightest particle with baryonic charge is a nucleon whose mass is $\simeq 1$ GeV. Therefore, such Q balls with $\omega_Q > 1$ GeV can decay into the nucleons (perhaps together with other lighter particles such as $\pi$-mesons). Since the decay can proceed only from the surface of the Q ball, the decay rate is bounded from above. For the MSSM Q ball, the rate is saturated and given
Entropy production by Q-ball decay for diluting long-lived charged particles

by [31]
\[ \Gamma_Q \simeq \frac{1}{Q} \frac{\omega_Q^3}{192\pi^2} 4\pi R_Q^3 \simeq \begin{cases} \frac{M_F \pi^2}{24\sqrt{2}} Q^{-5/4} & \text{for gauge-mediation type} \\ \frac{m_{3/2}}{24\pi |K|} Q^{-1} & \text{for gravity-mediation type.} \end{cases} \] (11)

Therefore, the decay temperature of the Q ball is calculated as
\[ T_D \equiv \left( \frac{\pi g_{*q}}{90} \right)^{-1/4} \left( \Gamma_Q M_P \right)^{1/2} \]
\[ \simeq \begin{cases} \frac{10 \text{ MeV}}{\tilde{\gamma}_{*q}^{1/4}} \left( \frac{M_F}{10^7 \text{ GeV}} \right)^{1/2} \left( \frac{Q}{10^{23}} \right)^{-5/8} & \text{for gauge-mediation type} \\ \frac{5 \text{ MeV}}{\tilde{\gamma}_{*q}^{1/4}} \left( \frac{|K|}{0.01} \right)^{-1/2} \left( \frac{m_{3/2}}{10 \text{ GeV}} \right)^{1/2} \left( \frac{Q}{10^{24}} \right)^{-1/2} & \text{for gravity-mediation type,} \end{cases} \] (12)

where \( g_{*q} \) counts the relativistic degrees of freedom at the Q-ball decay, and we define \( \tilde{\gamma}_{*q} \equiv g_{*q}/10.75 \) in the second equality.

3. Estimate of dilution factor

Let us now estimate how much the abundance of the stau is diluted in a situation where the Q ball releases entropy after it dominates the energy density of the universe. We define the dilution factor \( \Delta \) as
\[ \frac{n_{\tilde{\tau}}}{s} = \frac{1}{\Delta} \left( \frac{n_{\tilde{\tau}}}{s} \right)_{\text{thermal}}, \] (13)

where the left-hand side represents the ratio of the stau number density \( n_{\tilde{\tau}} \) to the entropy density \( s \) in the presence of the entropy production due to the Q-ball decay, while the abundance of the stau on the right-hand side is estimated without the entropy production. Note that, although we consider the Q-ball decay, our arguments in this section can be applied to any scenario where non-relativistic matter dominates the universe and decays with large entropy production.

The stau abundance can be diluted if the Q-ball decay takes place after the freeze-out of the stau. The dilution factor depends on the thermal history. We assume that the universe is radiation dominated before the Q balls start to dominate the energy density of the universe. Let us define \( T_{eq}, T_{fo}, \) and \( T_D \) as the temperatures when the Q-ball energy density becomes equal to the radiation density, the stau freezes out, and the Q ball decays, respectively. (We will use such notation that the subscripts eq, fo, and D denote that the variables should be estimated at \( T = T_{eq}, T_{fo}, \) and \( T_D \), respectively.) In figure 1 we sketch the evolution of the energy densities of the radiation, the Q ball, and the radiation produced by the Q-ball decay.
We now consider the following cases: (i) $T_{\text{eq}} < T_{\text{fo}}$ and (ii) $T_{\text{eq}} > T_{\text{fo}}$. In case (i), the situation is very simple, since the Q balls change the evolution of the universe after the freeze-out of the stau. We thus obtain
\begin{equation}
\left( \frac{n_{\tilde{\tau}}}{s} \right)_{\text{thermal}} \simeq \left( \frac{n_{\tilde{\tau}}}{s} \right)_{\text{eq}}. \tag{14}
\end{equation}
The dilution factor is calculated as
\begin{align}
\Delta &= \left( \frac{n_{\tilde{\tau}}}{s} \right)^{-1} \left( \frac{n_{\tilde{\tau}}}{s} \right)_{\text{thermal}} \\
&\simeq \left( \frac{s}{\rho_{Q}} \right)_{D} \left( \frac{\rho_{Q}}{n_{\tilde{\tau}}} \right)_{\text{eq}} \left( \frac{n_{\tilde{\tau}}}{s} \right)_{\text{eq}} \\
&\simeq \frac{T_{\text{eq}}}{T_{D}}, \tag{15}
\end{align}
where $\rho_{Q}$ is the energy density of the Q balls.

In the latter case (ii), the stau decouples from thermal equilibrium when the Q ball is dominating the universe. Therefore one needs to know the dependence of the stau number density on the Hubble parameter at the freeze-out. Since the freeze-out takes place when the annihilation rate becomes comparable to the expansion rate, we obtain
\begin{equation}
n_{\tilde{\tau}, \text{fo}} \sim \frac{H_{\text{fo}}}{\langle \sigma v \rangle}, \tag{16}
\end{equation}
where $\langle \sigma v \rangle$ is the thermally averaged cross section for the stau annihilation processes. The freeze-out temperature becomes larger than that in the usual radiation-dominated universe, since the energy density at the freeze-out is higher in the presence of the Q balls. However the change in $T_{\text{fo}}$ is not significant, because the stau decouples when it is non-relativistic, so the freeze-out temperature is rather insensitive to the change in the
cosmic expansion rate. Thus, we simply assume $T_{\text{fo}} \simeq m_{\tilde{\tau}}/20$ in the following\(^6\). Such an approximation is not essential to our arguments. Then we can estimate $\Delta$ as

$$\Delta \simeq \left( \frac{s}{\rho_Q} \right)_D \left( \frac{n_{\tilde{\tau}}}{n_{\tilde{\mu}}} \right)_{\text{fo}} \left( \frac{n_{\tilde{\mu}}}{s} \right)_{\text{thermal}},$$

where we use $\rho_Q \simeq 3H^2_{\text{fo}}M^2_P$ at the freeze-out, and $H^2_{\text{fo}}$ denotes the Hubble parameter at the freeze-out in the absence of the Q balls.

The relation between the Hubble parameter, $H_{\text{fo}}$, and the freeze-out temperature, $T_{\text{fo}}$, depends on whether the newly created radiation from the Q-ball decay dominates over the radiation that was present from the beginning, at the freeze-out of the stau. Let $T_{\text{tr}}$ denote the transition temperature at which the two radiation components become comparable to each other (see figure 1). In the case of $T_{\text{fo}} < T_{\text{tr}}$, we have

$$\Delta \sim \left( \frac{T_{\text{fo}}}{T_D} \right)^3,$$

where we use $T_{\text{tr}} \sim (T^3_{\text{eq}}T^2_D)^{1/5}$ and $H_{\text{tr}} \sim T^3_{\text{tr}}T^2_DM^{-1}$. On the other hand, in the case of $T_{\text{fo}} > T_{\text{tr}}$, we have $H_{\text{fo}} \sim (T^3_{\text{tr}}T_{\text{eq}})^{1/2}/M_P$. Substituting this into equation (17), we obtain

$$\Delta \sim \left( \frac{T_{\text{tr}}}{T_D} \right)^{3/2}.$$

In summary, we find that the dilution factor is given as follows depending on when the freeze-out takes place:

$$\Delta \sim \begin{cases} \frac{T_{\text{eq}}}{T_D} & \text{(Case A: } T_{\text{eq}} < T_{\text{fo}}) \\ \left( \frac{T_{\text{tr}}}{T_D} \right)^{1/2} & \text{(Case B: } T_{\text{tr}} < T_{\text{fo}} < T_{\text{eq}}) \\ \left( \frac{T_{\text{fo}}}{T_D} \right)^3 & \text{(Case C: } T_D < T_{\text{fo}} < T_{\text{tr}}) \end{cases}$$

Note that the decay temperature should lie in the range of $5 \text{ MeV} \lesssim T_D < T_{\text{fo}}$ \(^{32}\) and it must satisfy $T_D < T_{\text{eq}}$ in order to dilute the stau by the entropy production.

In the next section, we will determine the Q-ball-radiation equality temperature $T_{\text{eq}}$ by considering the formation and the dynamics of Q balls, in order to evaluate the dilution factor $\Delta$.

\(^6\) To include the change in $T_{\text{fo}}$, let us define $\gamma \equiv T_{\text{fo}}/T_{\text{\text{\text{'}}fo}}$, where $T_{\text{\text{\text{'}}fo}}$ denotes the freeze-out temperature for the modified cosmic expansion. It is estimated as $\gamma_B \sim 1 - (T/2m_{\tilde{\tau}})\log(T_{\text{eq}}/T_{\text{\text{\text{'}}fo}})$ for case B, and $\gamma_C \sim 1 - (2T/m_{\tilde{\tau}})\log(T_{\text{\text{\text{'}}fo}}/T_{\text{D}})$ for case C (see equation (20) and figure 1). The freeze-out temperature does not change in case A. As long as we stick to $\Delta \sim 10^3$, the minimum values of $\gamma_B \sim 0.1$, $\gamma_C \sim 0.7$, and our approximation seems to be valid. To take account of this change in $T_{\text{fo}}$, one has to multiply $\Delta$ in equation (20) by $\gamma \sim 1$ in the cases B and C with $T_{\text{\text{\text{'}}fo}}$ replaced with $T_{\text{\text{\text{'}}fo}}$. Then, one can see that $\Delta$ becomes larger by a factor of $\sim 4$ at most. Note that including the effect always increases the dilution factor.
4. Entropy production by the Q-ball decay

The Q-ball formation and the subsequent thermal history depend on the scalar potential at the onset of the oscillations. Since the large charge Q ball is necessary for a long lifetime, the field amplitude at the onset of the oscillation should be very large. In that case, the zero-temperature potential would be dominated by the gravity-mediation term (the second term in equation (1)). As we will see below, the thermal corrections are negligible for the parameters that we adopt in the following analysis.

The flat direction starts to oscillate when \( 3H \simeq m_{3/2} \). Here we simply assume that it takes place when the inflaton oscillation dominates the energy density of the universe. Then the ratio of the energy densities of the Q ball and the inflaton at the reheating is given by

\[
\left. \frac{\rho_Q}{\rho_{\text{inf}}} \right|_{\text{RH}} \simeq \frac{\rho_Q}{\rho_{\text{inf}}} \simeq \frac{(1/2)m_{3/2}^2\phi_{\text{osc}}^2}{3(m_{3/2}/3)^2M_p^2} \simeq \frac{3}{2} \left( \frac{\phi_{\text{osc}}}{M_p} \right)^2.
\]

(21)

After reheating the ratio evolves as \( \propto T^{-1} \), so the Q-ball-radiation equality temperature is obtained as

\[
T_{\text{eq}} \simeq T_{\text{RH}} \frac{3}{2} \left( \frac{\phi_{\text{osc}}}{M_p} \right)^2 \simeq 5 \text{ GeV} \left( \frac{T_{\text{RH}}}{8 \times 10^{-7} \text{ GeV}} \right) \left( \frac{\phi_{\text{osc}}}{5 \times 10^{14} \text{ GeV}} \right)^2.
\]

(22)

Meanwhile the decay temperature is calculated from equation (12) as

\[
T_D \simeq \left( \frac{\pi^2 g_{eq}}{90} \right)^{-1/4} \left( \frac{m_{3/2}^2M_p}{24\pi|K|} \right)^{1/2} \beta^{-1/2} \frac{m_{3/2}}{\phi_{\text{osc}}}
\]

\[
\simeq 5 \text{ MeV} \left( \frac{\phi_{\text{osc}}}{5 \times 10^{14} \text{ GeV}} \right)^{-1} \left( \frac{m_{3/2}}{10 \text{ GeV}} \right)^{3/2},
\]

(23)

where \(|K| = 0.01\) and \(g_{eq} = 10.75\). Since the freeze-out temperature is \( T_{\text{fo}} \simeq 5 \text{ GeV} \) for \( m_\pi = 100 \text{ GeV} \), the dilution factor is estimated as in case A:

\[
\Delta \sim \frac{T_{\text{eq}}}{T_D} \sim 10^3 \left( \frac{T_{\text{RH}}}{8 \times 10^{-7} \text{ GeV}} \right) \left( \frac{\phi_{\text{osc}}}{5 \times 10^{14} \text{ GeV}} \right)^3 \left( \frac{m_{3/2}}{10 \text{ GeV}} \right)^{-3/2}.
\]

(24)

In this case we have \( Q \simeq 10^{24}\). Notice that \( T_D \) shown in (23) can marginally satisfy the BBN constraints \([32]\). For slightly larger \( m_{3/2} \) or smaller \( \phi_{\text{osc}} \), one can have a large enough \( T_D \) that safely satisfies the BBN bound, keeping the dilution factor \( \Delta \) large enough. Since the initial amplitude of the flat direction is determined as in equation (3), it will be realized for the \( n = 6 \) direction (\( LLe \) or \( udd \)) with \( \lambda \simeq 0.006 \), or the \( n = 7 \) direction (\( dddLL \)) with \( \lambda \simeq 30 \). The coefficient of the thermal logarithmic corrections will be negative for these directions. If the thermal correction to the potential dominates over the gravity-mediation term, it will spoil the above scenario because the \( \Phi \) field will be trapped by the negative thermal logarithmic potential, and so it cannot be released for a long time. In order to avoid such a situation, we must impose the condition that the thermal logarithmic correction is negligible at the onset of the oscillations: \( \int_0^{T_{\text{osc}}} T_{\text{osc}}^{-1} < \frac{1}{2} m_{3/2}^2 \phi_{\text{osc}}^2 \).

\[7\] The thermal logarithmic term may not appear in such a situation where the dilute plasma before reheating is suppressed because of, e.g., the small mass of the inflaton and/or the existence of appropriate multiple flat directions.
Using \( T_{\text{osc}}^4 \simeq 0.5 H_{\text{osc}} M_P T_{RH}^2 \), it is rewritten as

\[
\phi_{\text{osc}} > \frac{f_T^2 T_{RH}}{\sqrt{3}} \left( \frac{M_P}{m_{3/2}} \right)^{1/2} \sim 2 \times 10^{14} \text{ GeV} \left( \frac{f_T}{0.1} \right)^2 \left( \frac{T_{RH}}{8 \times 10^7 \text{ GeV}} \right) \left( \frac{m_{3/2}}{10 \text{ GeV}} \right)^{1/2},
\]

which is satisfied in the above analysis.

Finally, we comment on the last moment of the Q-ball decay. As the charge becomes small, the gravity-mediation type Q ball gradually deforms into the gauge-mediation type one. Therefore, at a certain point, the mass per unit charge of the Q ball may exceed the stau mass, \( \omega_Q > m_{\tilde{\tau}} \), which implies that the stau can be produced. In order to suppress the stau abundance as \( Y_{\tilde{\tau}} \lesssim 10^{-17} \), we must impose \( M_F \lesssim 10^5 \text{ GeV} \). This is because \( Y_{\tilde{\tau}} \sim B_{\tilde{\tau}}(T_D/m_{3/2}) \) and the branching ratio is estimated as \( B_{\tilde{\tau}} \sim Q_{\text{cr}}/Q \) where \( Q_{\text{cr}} \sim (M_F/m_{\tilde{\tau}})^4 \). Such a small value of \( M_F \) is realized in a model where the Yukawa coupling \( \kappa \) is suppressed as in the case of the composite \( S \) field.

5. Conclusion

We have shown that the Q-ball decay can produce large enough entropy to dilute the cosmic abundance of a long-lived charged particle such as a stau. Since the Q balls are composed of the MSSM particles, our scenario is minimal in some sense. Successful late-time entropy production is not so easily achieved as one might think: the particle that produces entropy should have a smaller mass than the stau and a long lifetime, and no unwanted particle production should occur. In our scenario, a large charge \( Q \) naturally makes the effective mass smaller than the stau mass, and the decay products are just the SM particles. It also explains the longevity of the Q ball. The large Q ball can be naturally produced in the dynamics of the flat direction.

In addition, we have derived analytically the dilution factor for the cases where the stau freezes out both before and after the Q ball starts to dominate the universe.

Lastly let us briefly discuss the baryon asymmetry and dark matter. Due to the late-time entropy production, the baryon asymmetry and the gravitino dark matter are also diluted. One way out is to overproduce both by the amount of the dilution beforehand. Another is to create them after the entropy production. As for the gravitino dark matter, the thermal production does not suffice since the reheating temperature cannot be too high due to the constraint (25). Therefore, one has to rely on the non-thermal production [7,33]. On the other hand, one can obtain the right magnitude of the baryon asymmetry from the Q-ball decay itself, making use of the Affleck–Dine baryogenesis. If the flat direction has the baryon number, it must start the oscillations with suppressed angular motion (i.e., \( \epsilon \sim O(10^{-7}) \)). On the other hand, for the leptonic direction, the lepton charges evaporated from the Q ball before the electroweak phase transition are partially converted into baryon asymmetry through the sphaleron processes. In this case, \( \epsilon \sim O(10^{-3}) \) is necessary to get the right abundance of baryon asymmetry.
