Abstract. Methane brown dwarfs (CH\textsubscript{4}BDs), i.e. objects similar to the low mass star Gliese 229B, are characterized by very unusual colours: J–K\textsubscript{eff} ≤ 0 and I–J \textsubscript{eff} > 5. An analysis of the ESO public images, which cover an area of 37 sq. arcmin in the three filters, yields one clear CH\textsubscript{4}BD candidate with J\textsubscript{eff} = 20.2 and two fainter sources with J\textsubscript{eff} ≃ 23. The resulting observed density of methane dwarfs ranges from \( \approx 100 \) to \( \approx 500 \) objects per sq. degree with J < 23.1, quite high but compatible, within the errors, with what we derive from simulations of the stellar population of brown dwarfs in the disk of the Galaxy adopting reasonable (although still speculative) hypotheses on the evolution of BD colours with cooling. The predictions presented here can be useful in constraining the results from future searches of these objects in the infrared. Deep imaging of several sq. degrees of sky down to J > 22, K > 22 and I > 27 are necessary to significantly improve the observational database.

1. Introduction

Until recently, only three very low luminosity objects were known with spectral type later than M\textsubscript{9.5}, but the two near IR ground based surveys DENIS and 2MASS opened a new window in the study of the end of the main sequence and its continuation into the realm of Brown Dwarfs (BDs). In fact, DENIS added three objects (Delfosse et al. 1997, Tinney et al. 1998), and 2MASS (Kirkpatrick et al. 1998) increased this sample till now by about 20 objects spectroscopically confirmed by the Low Resolution Infrared Spectrometer at Keck. These findings are defining a new spectral class, the “L dwarfs” spanning \( T_{\text{eff}} \approx 2200–1500 \) K, their exact temperatures depending on the treatment of dust in model atmospheres.

It was recently recognized that the near IR colours of the late M dwarfs (\( T_{\text{eff}} \lesssim 2600 \) K) could not be reproduced by model atmospheres, unless they included consideration of grains. Although the spectral feature are very complex, the first generation of model atmospheres including grain condensations (Tsuji et al. 1996, Allard 1998) are able to interpret the main emerging spectral characteristics, and include predictions also for the L-dwarf spectra. Dust grains forming in the upper layers of very cool dwarfs have a large opacity, and produce a redistribution of the IR flux (greenhouse effect), explaining the very red J–K colours of the latest M and of the L-dwarfs. The L-dwarfs clearly define the low end of the MS, which, depending on the opacity, and thus on the dust inclusion in the models, may be shifted even as low as \( \sim 1800 \) K (Burrows and Sharp 1999). However, due to the steepness of the mass luminosity relation around the hydrogen burning minimum mass (D’Antona & Mazzitelli 1988), the range of \( T_{\text{eff}} \)’s of L-dwarfs should be mostly populated by cooling brown dwarfs. An indication confirming this interpretation is the presence of Lithium in about half of the 2MASS objects, indicating that they are unable to burn their initial lithium, and thus that their mass is below \( \sim 0.06 \) \( M_{\odot} \) (see however Allard 1998 for a different interpretation).

When L-dwarfs evolve further, they will eventually reach \( T_{\text{eff}} < 1500 \) K. Just as for normal white dwarfs, the evolutionary time is dictated by the release of the thermal energy of the ions, so that it increases when decreasing the luminosity. Only one object was until recently identified as the result of such cooling: the companion to the low mass star Gliese 229, having a spectrum showing the CH\textsubscript{4} bands, predicted by theory. This object, the “Rosetta stone” of cool BDs, at \( T_{\text{eff}} \approx 900 \) K and luminosity well below \( 10^{-5}L_{\odot} \) (Leggett et al. 1999), shows in fact a peculiar spectrum characterized by metal depletions, and dominated by H\textsubscript{2}O, CH\textsubscript{4} and alkali metals. The flux redistribution at very low \( T_{\text{eff}} \) produces a spectrum much bluer in J–K, while keeping a very red I–K colour (e.g. Burrows et al. 1997). Therefore, while the typical colour of L-dwarfs are J–K > 1.3 (e.g. Leggett et al. 1998), the cooler BDs should have J–K < 0, as confirmed by the colour of Gliese 229B (Nakajima et al. 1997, Legget et al. 1999).

Although this outline of low mass and brown dwarf evolution is qualitatively sound, we are quite far from a complete theoretical understanding of the problem. At the upper mass end (\( M \gtrsim 0.4M_{\odot} \)) the inclusion of molecular opacities in the model atmospheres, and the use of bound-
Fig. 1. HR diagram with the evolutionary tracks of low mass stars. The dashed lines are from D’Antona & Mazzitelli (1997) and cover the 0.6 to 0.2 $M_\odot$ range, while the tracks for lower mass stars (0.237 to 0.03 $M_\odot$) are from Burrows et al. (1998). The square symbols mark the positions at $10^{10}$ years. The approximate boundaries of the M, L and methane dwarfs are shown. The Main Sequence limit is between 2000 and 1800K depending on the opacities adopted, so it falls in the middle of the L spectral type.

Fig. 2. Selected regions of the ESO deep fields showing the $CH_4$ BDs candidates. Each sub-frame is 28"x28" with N to the left and E to the bottom, the position of the candidate is marked by a white rectangle. The object magnitudes and colours are $\pm 0.15$ while the upper limits are at the 3$\sigma$ level.

2. Observational constraints on the density of faint $CH_4$ BDs

In spite of all the difficulties in the models, the very blue J–K colour, together with a very red I–K, should be a signature of the very low $T_{\text{eff}}$, older BDs which we will call $CH_4$ BDs. This simple recognition has prompted us to search for faint objects characterized by small J–K but very large I–K or R–J, indicative of low $T_{\text{eff}}$. A very useful data set comes from the ESO public survey data which

are targeted at regions far from the galactic plane and include the NTT SUSI deep field (\(l=284^\circ, b=+53^\circ\), Arnouts et al. 1999, Moorwood et al. 1998), the EIS HDF–S field (\(l=328^\circ, b=-49^\circ\), da Costa et al. 1999) and the AXAF deep field (\(l=224^\circ, b=-54^\circ\), Rengelink et al. 1999). The overlap between infrared (K, J) and optical (I, R, V) images cover a total area of 37 sq. arcmin and is complete to K=22.6, J=24.4 and I=26.3 mag. These limits are somewhat unbalanced for our purposes, i.e. too shallow in K and I for the depth reached in J. The colour selection we use to extract methane dwarf candidates effectively translates into a cut at J=23.1 and much above the limit of completeness of the J images.

The methane dwarf candidates were selected as those point–like objects with J–K < 0.5 and I–J > 3, i.e. colours which are incompatible with any known stellar source other than GL229B. This yielded three objects whose finding charts and magnitudes are shown in Fig. 3. Considered the statistical errors, the corresponding density ranges between \(\approx\) 100 and \(\approx\) 500 objects per sq. degree with magnitudes J<23.1.

In should be noted that the colours of the selected objects are also compatible with quasars or QSOs at \(z\approx 9\), i.e. at redshifts where the Ly\(\alpha\) falls into the J band and the Lyman–break is moved beyond the I photometric band. In such a case an observed magnitude J=23 would translate into an absolute blue magnitude M\(_{B}\) \approx -25 and typical of low–medium luminosity QSOs. However, we consider this possibility unlikely because current estimates of the density of quasars at various redshifts indicate a rapid drop beyond \(z=3\) with basically no object at \(z > 6\) (e.g. Shaver et al. 1996). Encouragingly, the CH\(_4\)BD nature of the brightest object was recently confirmed by spectroscopic IR observations at the VLT (Cuby et al. 1999).

3. Modelling of number counts and predicted colours

As outlined in the introduction, it is not possible to model self–consistently the whole BD evolution. We decided therefore to adopt an admittedly rather simple–minded approach to the colour derivation, in order get a first estimate of the expected number counts of CH\(_4\)BDs. On the other hand, we took care to model carefully the galactic disk, so that the global model can be easily improved when more precise evolutionary tracks will be available.

3.1. The theoretical models

As a first input, we need the time evolution of log\(L/L_{\odot}\) and \(T_{\text{eff}}\) for stellar masses which trace the low end of the main sequence and the brown dwarf evolution. We will use as a basis the models by Burrows et al. 1997 and private communication) employing non gray model atmospheres up to 1300K, and similarly low resolution non gray models with grains up to 2400K. Above this temperature, gray models with Rosseland opacities from Saumon are adopted. These tracks are computed for masses from...
The density of CH$_4$ Brown Dwarfs

Fig. 4. Stellar counts (in bins of 0.5mag, per square degree) as function of the apparent J magnitude for three selected mass ranges.

0.237$M_\odot$ to 0.03$M_\odot$, and are evolved up to an age of 20Gyr, which is reached at quite low $T_{\text{eff}}$ for the smaller masses, so they constitute a very complete set to deal with all the very low mass and brown dwarf regimes, from the M spectral type, through the L dwarfs, to the postulated CH$_4$BDs phase. Above this mass, for the purpose of having predictions available also for somewhat hotter stars, we adopt the tracks by D’Antona and Mazzitelli (1997) from 0.25 to 0.8$M_\odot$. Although the latter are computed with somewhat different inputs (e.g. the deuterium initial abundance is a half of the abundance assumed by Burrows et al., the treatment of over–adiabatic convection is different) the merging of the two sets is very reasonable, also because mainly the main sequence or cooling part of the sequences are important to determine the stellar counts. The gray atmosphere low mass models by D’Antona and Mazzitelli (1997) predict luminosities larger by $\sim 15\%$ (generally $<0.1\text{mag}$) than the non gray models e.g. by Chabrier & Baraffe (1997, hereafter CB97) and have $T_{\text{eff}}$ $\sim 2\%$ larger. The Burrows et al models above 2400K compare well with those of CB97 in luminosity, and they differ by 2\% in $T_{\text{eff}}$.

3.2. Colours and bolometric corrections

The magnitudes in I, J and K are not directly available in the track sets, so we decided to adopt the admittedly crude procedure of estimating the I and J band bolometric corrections ($BC$) from the CB97 models, which are consistent with the CB97 models. The B98 values have been used for $T_{\text{eff}}> 2000$ K. We extrapolate these $BC$s to $T_{\text{eff}}=600$ K using the models of Burrows et al. (1997). We remark that the J band counts should be little affected by uncertainties in the bolometric corrections. In fact, $BC_J$ is 2.19mag at 2000K, and very similar (2.23mag) at $T_{\text{eff}}=600$ K (see table 1). In other words, 25–30\% of the flux for these objects emerges in the J band, regardless of their temperature (e.g. Burrows et al. 1998).

The colours J–K are taken from Burrows et al. 1998 for $T_{\text{eff}}\leq1000$ K. Above 3300 K we adopt the colours of B98. In the intermediate range, these models fail reproduce the observations of cooler dwarfs (Leggett et al. 1998, B98) and computations including grains should be used (e.g. Allard 1998, Jones & Tsuji 1998) to get the very red J–K colours down to GD165B. However, dusty models are still very incomplete and we therefore employed a semiempirical approximation, imposing the models to pass through the colour of GD165B and then to evolve to the blue. Table 1 shows the adopted relation between $T_{\text{eff}}$ and J–K. The reader should be well aware that this approach...
represents an educated guess on the CH$_4$BDs colour evolution. Nevertheless the semiempirical approach mainly influences the relative number counts of the J versus K band, but not the $T_{\text{eff}}$ selection, which however is itself is uncertain in the absence of better modeling.

3.3. The integrated number counts

The number of stars within a given range of temperature ($T_{\text{eff}}$+$\Delta T$) and apparent magnitude (J+$\Delta J$) expected from observations directed at a given direction $l$, $b$ (galactic coordinates) and covering a relatively small solid angle $\Omega$ is given by

$$\Sigma(T_{\text{eff}},J) = \int_{0}^{\infty} \Phi[T_{\text{eff}},(J-5\log R_{10})] \rho(R) \, \Omega \, R^2 \, dR$$

where $R$ is the distance from the sun along the $l,b$ line of sight, $R_{10}=(R/10 \, \text{pc})$ and $\rho$ is the total stellar density whose radial dependence can be approximated by (Bachall & Soneira, 1978)

$$\rho(R) = \rho_o \, \exp(-z/H - (r-r_o)/h)$$

$$z = R \sin b$$

$$r = \sqrt{(R \cos b)^2 - 2R r_o \cos b \cos l + r_o^2}$$

The coordinate $z$ is measured perpendicular to the galactic plane, $r$ is the radial distance from the galactic center and $r_o=8 \, \text{kpc}$ is the distance of the Sun. The scale height is $H=325 \, \text{pc}$, consistent with the counts of M dwarfs, and the scale length is $h=3.5 \, \text{kpc}$. The local stellar density $\rho_o$ is given by

$$\rho_o = 0.336 \int_{M_{\text{min}}}^{M_{\text{max}}} \left( \frac{M}{0.1 \, M_\odot} \right)^{-(1+z)} \, dM$$

where we have adopted a power law initial mass function $dN/dM \propto M^{-(1+z)}$ and the normalization factor at $0.1 \, M_\odot$ is taken from Reid & Gizis (1997). The mass limits considered here are $M_{\text{min}}=0.03 \, M_\odot$ and $M_{\text{max}}=0.8 \, M_\odot$.

In Eq. (1) the term $\Phi(T_{\text{eff}},M_1)$ gives the fraction of stars within the selected range of temperature and absolute J magnitude, i.e. the relative density of stars on a given position of the theoretical $T_{\text{eff}}$–$M_1$ HR diagram. This function, which depends on the shape of the IMF and on star formation history, is constructed via a Montecarlo technique assuming an uniform birth-rate from $t=0$ to the present disk age $t_{\text{disk}}=10 \, \text{Gyr}$. The program randomly extracts masses (with probability given by the chosen IMF shape) and ages from the track sets of Fig. 1. Each extraction provides a point in the $M_{\text{bol}}$–$T_{\text{eff}}$ diagram which translates into absolute magnitudes using the bolometric corrections of Table 1. The extracted stars are grouped into suitably small bins of temperatures and $M_1$, this yields the matrix which represents the function $\Phi$ which is used to compute the integral of Eq. (1).

![Fig. 6. Example of the predicted distribution of apparent stellar J magnitudes versus J–K colour for observations covering of 1 square degree. The points cluster along the main sequence defined by the thick part along J–K$\simeq$1, then we recognize the L–dwarfs which populate the region at 1<J–K<1.6, before evolving to much bluer colours when the methane bands begin to appear in the atmosphere.](image-url)

3.4. Results

The distribution of the apparent magnitude J as a function of the distance (Fig. 2) shows that the bulk of M dwarfs is at magnitudes $J<20$, where BDs begin to appear. L–dwarfs are numerous at $J\sim20–22$, while CH$_4$BDs begin to be common only at $J>21$.

Fig. 2 and Fig. 3 also show the same feature. The first displays the number counts per J magnitude within three mass bins: dwarfs ($0.5–0.7 \, M_\odot$), low mass dwarfs ($0.08–0.14 \, M_\odot$) and brown dwarfs (below 0.08 $M_\odot$). Being relatively bright, the dwarfs show a maximum in the distribution at $J \simeq 17$, the lowest mass dwarfs also show a maximum at $J \simeq 20$, while the BDs number increases down to the limit at which we count them ($J=25$). Therefore, either very deep searches are necessary to show an appreciable number of CH$_4$BDs, or a relatively deep survey covering most of the sky. Fig. 3 shows the total number counts versus J magnitude, putting into evidence which mass ranges contribute to its different parts. The broad maximum in the counts at $J=17–19$ includes only dwarfs and results from the combination of the effects due to the IMF, the mass luminosity relation for the main sequence and the radial density distribution. The rising of the number counts at $J>22$ is instead due to the low mass brown

dwarfs. Finally, Fig. 3 shows simulated J vs J-K colour–magnitude diagram for observations covering 1 sq. degree of sky. The large scatter of J-K colours for the $CH_4BDs$ reflects the effect of methane bands absorption on the J–K colour, which is expected to increase rapidly between $T_{eff}=1000$ K ($J-K=0.1$) and $T_{eff}=600$ K ($J-K=1.4$, see Table 3).

The resulting counts are tabulated in Table 2 for galactic coordinates similar to those of the ESO fields, namely $b=55^\circ l=340^\circ$, and at the galactic pole ($b=90^\circ$).

3.5. Comparison with observations

Table 2 shows that a considerable number of L–dwarfs are predicted, but practically no $CH_4BDs$ (at most 1 in 1000 sq. degrees), in a large area limited at K $<14.5$, in agreement with the early results of 2MASS. The very recent observations of four relatively bright $CH_4BDs$ (Strauss et al. 1999, Burgasser et al. 1999) yields a surface density of ≃0.002 cool methane dwarfs with J $<16$ and a factor of 3–6 lower than those predicted here using flat and steep IMFs, respectively, and considering only the density of objects of $T_{eff}<1400$ K. However, these differences are not necessarily significant, given the small number of objects detected and the possibility that the the above searches may not be yet complete.

Our observed density of 3 objects with J $<23.1$ within 37 sq. arcmin is consistent (i.e. within the Poisson’s noise) with the space density predicted using a relatively steep IMF ($x=1$) while it is a factor of 4±2 larger than expected from a flatter IMF ($x=0$). Remember that this latter IMF is certainly more consistent with the slope derived from nearby low mass stars (Reid and Gizis 1997). Given the very small number of objects detected we consider it premature to draw strong conclusions about the IMF.
4. Conclusions

We presented three $\text{CH}_4\text{BD}$s candidates with $J<23.1$ found in an area of 37 sq. arcmin covered by the ESO public images survey and modelled the expected number counts for these objects as well as for L and M dwarfs. Theoretical predictions are made on the basis of a sound galactic model including the most complete set of today’s available evolutionary tracks and colours–$T_{\text{eff}}$ correlations. The model could be significantly improved only when self-consistent computations will be available, including model atmospheres tested on the methane dwarfs which will be discovered.

The predicted surface densities are in reasonably good agreement with the observed counts of L dwarfs and with the sparse observational data presently available for methane dwarfs, namely the lack of objects with $K<14.5$ in the early 2MASS survey, the recent finding of four relatively bright ($J<16$) $\text{CH}_4\text{BD}$s in 1800 sq. degrees and the three much fainter candidates discussed here.

We also showed that, due to their very low intrinsic luminosities, methane dwarfs become numerous (relative to L and M dwarfs) only at very faint $J$ magnitudes (see figures from 3 to 6). To significantly improve the observational database it is therefore necessary to cover a reasonably large area of sky (several sq. degrees) down to $J\approx22$, as well as $K\approx22$ and $I\approx27$, the latter two being necessary for selecting the $\text{CH}_4\text{BD}$ candidates. We look forward for this type of observations to be soon performed by the IR large field deep imagers operating or planned on large telescopes.

Acknowledgements. We are grateful to ESO for making the EIS and NTT SUSI Deep field data available to the community. The EIS observations have been carried out using the ESO New Technology Telescope (NTT) at the La Silla observatory under Program-ID Nos. 59.A-9005(A) and 60.A-9005(A). This work was partly supported by the Italian Ministry for University and Research (MURST) under grant Cofin98-02-32. We thank A. Burrows for helpful discussion and G. Chabrier for a careful referee’s report.
