Fidelity-based Probabilistic Q-learning for Control of Quantum Systems
Chunlin Chen, Daoyi Dong, Han-Xiong Li, Jian Chu, Tzyh-Jong Tarn

Abstract—The balance between exploration and exploitation is a key problem for reinforcement learning methods, especially for Q-learning. In this paper, a fidelity-based probabilistic Q-learning (FPQL) approach is presented to naturally solve this problem and applied for learning control of quantum systems. In this approach, fidelity is adopted to help direct the learning process and the probability of each action to be selected at a certain state is updated iteratively along with the learning process, which leads to a natural exploration strategy instead of a pointed one with configured parameters. A probabilistic Q-learning (PQL) algorithm is first presented to demonstrate the basic idea of probabilistic action selection. Then the FPQL algorithm is presented for learning control of quantum systems. Two examples (a spin-$\frac{1}{2}$ system and a $\Lambda$-type atomic system) are demonstrated to test the performance of the FPQL algorithm. The results show that FPQL algorithms attain a better balance between exploration and exploitation, and can also avoid local optimal policies and accelerate the learning process.

Index Terms—Fidelity, probabilistic Q-learning, quantum control, reinforcement learning.

I. INTRODUCTION

REINFORCEMENT learning (RL) [1] is an important approach to machine learning, control engineering, operations research, etc. RL theory addresses the problem of how an active agent can learn to approximate an optimal behavioral strategy while interacting with its environment. RL algorithms, such as the temporal difference (TD) algorithms [2] and Q-learning algorithms [3], have been deeply studied in various aspects and widely used in intelligent control and industrial applications [4]-[17]. However, there exist several difficult issues in developing practical applications from RL methods. These difficult issues include tradeoff between exploration and exploitation, function approximation methods and speed-up of the learning process. Hence, new ideas are necessary to improve reinforcement learning performance. In [18], we considered two features (i.e., quantum parallelism and probabilistic phenomena) from the superposition of probability amplitudes in quantum computation [19] to improve TD learning algorithms [18], [20], [21]. Inspired by [18], this paper focuses on only the probabilistic essence of decision-making in Q-learning [22] with fidelity-directed exploration strategy, and propose a fidelity-based probabilistic Q-learning method for the control design of quantum systems.

We focus on exploration strategies (i.e., action selection methods), which contribute to better balancing between exploration and exploitation and have attracted more and more attention from different areas [23]-[30]. For Q-learning, exploitation (i.e., the greedy action selection) occurs if the action selection strategy is based on only current values of the state-action pairs. In most optimization problems, this will lead to locally optimal policies, possibly differing from a globally optimal one. In contrast, exploration is a strategy based on the assumption that the agent selects a non-optimal action in the current situation and obtains more knowledge about the problem. This knowledge allows the agent to neglect the locally optimal policies and to reach the globally optimal one. However, excessive exploration will drastically decrease the performance of a learning algorithm. Generally in a reinforcement learning process without prior knowledge or training data, most of existing exploration strategies are undirected exploration. Up to now, there have existed two main types of undirected exploration strategies: $\epsilon$-greedy strategy and randomized strategy [1], where the randomized strategy includes such methods as Boltzmann exploration (i.e., Softmax method) and simulated annealing (SA) method [1], [23]. These exploration strategies usually suffer from difficulties in balancing between exploration and exploitation, and providing an easy mechanism of parameter setting. Hence, the aim of this paper is to propose a novel fidelity-based probabilistic action selection method to improve Q-learning algorithms.

In this approach, we systematically investigate the use of probabilistic action selection mechanism (e.g., see [31] and Section 6.6 in [1]) to dynamically balance the exploration and exploitation in reinforcement learning. Furthermore, a fidelity-based probabilistic Q-learning algorithm is presented for learning control of quantum systems. The development of control design approaches for quantum systems is a key task for powerful quantum information technology [19], [32]-[38]. Unique characteristics of quantum systems (e.g., ultrafast dynamics, measurement destroying quantum states) make open loop strategies competitive [32], [33]. Here we employ a reinforcement learning approach to design control laws for a class of quantum control problems where the set of control
fields is given. Once the control sequence is obtained by learning, the corresponding control fields can be applied to the quantum system to be controlled. The method is very useful for quantum systems since it is an important objective to find control laws for complex quantum control problems when we have limited resources. However, if we employ a basic reinforcement learning algorithm, the direction of achieving the objective is always delayed due to the lack of feedback information during the learning process unless the agent reaches the target state. Hence, the learning process is time-consuming and the agent learns very slowly, which impedes the applications of reinforcement learning methods to complex learning problems with large learning space. In quantum information theory, the “closeness” between two quantum states can be measured by fidelity [19], [39], [40]. The more similar two quantum states are, the greater the fidelity between the two states is. For example, the fidelity of two identical quantum states is usually defined as 1 and the fidelity of two orthogonal quantum states is defined as 0. The fidelity F between two quantum states corresponds to a non-negative number F ∈ [0, 1]. Hence, the information of fidelity can be sent back to the learning system and help speed up the learning process as a global direction signal to avoid getting lost. Recent research on quantum control landscapes provides a theoretical footing for the development of new learning algorithms using the information of fidelity [41], [42]. Numerical examples show that the fidelity-based probabilistic Q-learning method has improved performance for learning control of quantum systems.

This paper is organized as follows. Section II introduces the basic Q-learning method and the existing exploration strategies. In Section III, the probabilistic action selection strategy is presented. Then a probabilistic Q-learning (PQL) algorithm and a fidelity-based PQL (FPQL) algorithm are proposed and analyzed aiming at speeding up the learning process. In Section IV, the FPQL algorithm is applied to learning control of two typical classes of quantum systems (a spin-1/2 system and a Λ-type atomic system), respectively. Conclusions are given in Section V.

II. Q-LEARNING AND EXPLORATION STRATEGY

Q-learning can acquire optimal control policies from delayed rewards, even when the agent has no prior knowledge of the environment. For the discrete case, a Q-learning algorithm assumes that the state set S and action set A can be divided into discrete values. At a certain step t, the agent observes the state st, and then chooses an action at. After executing the action, the agent receives a reward rt+1, which reflects how good that action is (in a short-term sense). The state will change into the next state st+1 under action at. Then the agent will choose the next action at+1 according to the best known knowledge. The goal of Q-learning is to learn a policy π : S × A → [0, 1], so that the expected sum of discounted rewards for each state will be maximized:

$$Q^\pi(s, a) = r_a + \gamma \sum_{s'} \sum_{a'} p_{ss'aa'} Q^\pi(s', a')$$

where $\gamma \in [0, 1]$ is a discount factor, $p_{ss'aa'} = Pr\{s_{t+1} = s' | s_t = s, a_t = a\}$ is the probability for state transition from s to $s'$ with action $a$, $p^\pi(s', a')$ is the probability of selecting action $a'$ for state $s'$ under policy $\pi$ and $r^\pi_a = E\{r_{t+1} | s_t = s, a_t = a\}$ is an expected one-step reward. $Q(s, a)$ is called the value function of state-action pair $(s, a)$. Let $a_t$ be the learning rate. The one-step updating rule of Q-learning may be described as:

$$Q(s_t, a_t) \leftarrow (1 - \alpha_t)Q(s_t, a_t) + \alpha_t(r_{t+1} + \gamma \max_a Q(s_{t+1}, a')).$$

The optimal value function $Q^*_{\pi(s, a)}$ satisfies the Bellman equation (1):

$$Q^*_{\pi(s, a)} = \max_a Q(s, a) = r_s + \gamma \sum_{s', a'} p_{ss'a'} \max_a Q^*_{\pi(s', a')}.$$ 

More details about Q-learning can be found in [1], [3]. To efficiently approach the optimal policy $Q^*$, one widely used action selection method is the $\varepsilon$-greedy method, the “best” action is still given the highest greedy strategy. In addition, the exploration probability $\varepsilon$ can be reduced over time, which moves the learning from exploration to exploitation. The $\varepsilon$-greedy method is simple and effective, but it has the drawback that when the learning system explores it chooses equally among all actions. This means that the learning system makes no difference between the worst action and the next-to-best action. Another problem is that it is difficult to choose a proper parameter $\varepsilon$ for the optimal balance between exploration and exploitation.

Another kind of action selection methods is randomized strategies, such as the Softmax method [1] and the simulated annealing method [23]. Such methods use a positive parameter $\tau$ called a temperature and choose an action $a$ with the probability proportional to $\exp(Q(s, a)/\tau)$. Compared with the $\varepsilon$-greedy method, the “best” action is still given the highest selection probability, but all the others are ranked and weighted according to their estimated $Q$-values. It can also move from exploration to exploitation by adjusting the “temperature” parameter $\tau$. It is natural to sample actions according to this distribution, but it is very difficult to set and adjust a good parameter $\tau$ and may converge slowly. Another shortcoming is that it does not work well when the $Q$-values of the actions are close and the best action cannot be separated from the others. Moreover, when the parameter $\tau$ is reduced over time to acquire more exploitation, there is no effective mechanism to guarantee re-exploration when necessary.

To sum up, these existing exploration strategies usually suffer from difficulties in balancing between exploration and exploitation, setting appropriate parameters and providing an effective mechanism of re-exploration. Here, we present a novel fidelity-based probabilistic Q-learning algorithm where...
a probabilistic action selection method is used as more effective exploration strategies to improve the performance of Q-learning for complex learning control problems. Compared with $\epsilon$-greedy and Softmax methods, Fig. 1 shows the illustration of the ideas of straightforward probabilistic action selection method and the fidelity-based one, where a longer line with an arrow indicates a higher probability. As shown in Fig. 1(a), $\epsilon$-greedy method uses a prefixed exploration policy and the action $a_1$ with the maximum of Q-value ($Q(s,a_1)$) is selected with the probability of $(1-\epsilon)$ and all the other actions ($a_2 \sim a_m$) are select with the probability of $\epsilon/(m-1)$, respectively. Using Softmax method (Fig. 1(b)), the action $a_i$, $i=1,2,\ldots,m$, is selected with the probability of $e^{Q(s,a_i)/\tau}$ in Fig. 1(c) shows that the action selection probability distribution is dynamically updated (denoted with the dashed line) along with the learning process instead of being computed from the estimated Q-values and a temperature parameter. In Fig. 1(d), the fidelity is used to direct the probability distribution and to strengthen the learning effects with a regulation on the updating process. These different exploration policies will be further explained and compared from a point of view of physical mechanism (as shown in Fig. 4) after the PQL and FPQL method are systematically presented in the next section.

III. FIDELITY-BASED PROBABILISTIC Q-LEARNING

A. Probabilistic Action Selection and Reinforcement Strategy

Inspired by the work in [18], [20], we reformulate the action selection strategy in a unified probabilistic representation where the action selection probability distribution is updated based on the reinforcement strategy. The discrete probability distribution on the state-action space is defined as follows.

Definition 1: The probability distribution on the state-action space (discrete case) of a RL problem is characterized by a probability mass function defined on the state set $S$ and the action set $A = \bigcup_{s \in S} A(s)$, where $A(s)$ is the set of all the permitted actions for state $s$. For any $s \in S$ and $a \in A(s)$, the probability mass function is defined as $p(s,a) \geq 0$ and for a certain state $s$, it satisfies

$$\sum_{a \in A(s)} p(s,a) = 1. \quad (4)$$

Suppose the state-action space is $S \times A$, where

$$S = \{s_1, s_2, \ldots, s_n\} \quad (5)$$

$$A = \bigcup_{s \in S} A(s) = \{a_1, a_2, \ldots, a_m\}. \quad (6)$$

From Definition 1, the policy to be learned $\pi : S \times A \rightarrow [0,1]$ can be represented using the probability distribution of the state-action space

$$\pi : P^\pi = (p^\pi(s,a))_{n \times m} \quad (7)$$

where $s \in S$, $a \in A$ and for a certain state $s$, the probability distribution on the action set $A$ is $p^\pi_s = \{p^\pi(s,a)\}, i = 1,2,\ldots,m$. The look-up table for the Q-values and the probability distribution are of the form

$$\begin{pmatrix}
a_1 & a_2 & \cdots & a_m \\
Q(s_1,a_1) & Q(s_1,a_2) & \cdots & Q(s_1,a_m) \\
\pi_{s_1} & \pi_{s_1} & \cdots & \pi_{s_1} \\
Q(s_2,a_1) & \pi_{s_2} & \cdots & \pi_{s_2} \\
\vdots & \vdots & \ddots & \vdots \\
Q(s_n,a_1) & \pi_{s_n} & \cdots & \pi_{s_n} \\
p^\pi_{s_1} & p^\pi_{s_1} & \cdots & p^\pi_{s_n}
\end{pmatrix} \quad (8)$$

Fig. 2 shows a 3-D illustration of the probabilistic distribution on the state-action space for action selection under current policy $\pi$. In the probabilistic action selection method, one selects an action $a$ (under policy $\pi$) at a certain state $s$
with the probability according to the probability distribution on the action set $A$, i.e.,

$$a_s^\pi = f^\pi(s) = \begin{cases} a_1 & \text{with probability } p^\pi(s, a_1) \\ a_2 & \text{with probability } p^\pi(s, a_2) \\ \vdots \\ a_m & \text{with probability } p^\pi(s, a_m) \end{cases}$$  \hspace{1cm} (9)$$

Such a probabilistic action selection method leads to a natural probabilistic exploration strategy for Q-learning.

The goal of PQL is to learn a mapping from states to actions. The agent needs to learn a policy $\pi$ to maximize the expected sum of discounted reward for each state:

$$Q^\pi_{(s,a)} = \sum_{a \in A(s)} p^\pi(s,a)\left[r_s^a + \gamma \sum_{s'} p_{s'|s}Q^\pi_{(s',a')}\right].$$  \hspace{1cm} (10)$$

The one-step updating rule of PQL for $Q(s,a)$ is the same as that of QL:

$$Q(s_t, a_t) \leftarrow (1 - \alpha_t)Q(s_t, a_t) + \alpha_t(r_{t+1} + \gamma \max_{a'} Q(s_{t+1}, a')).$$  \hspace{1cm} (11)$$

Besides the updating of $Q(s,a)$, the probability distribution is also updated for each learning step. After the execution of action $a_t$ at state $s = s_t$, the corresponding probability $p(s_t, a_t)$ is updated according to the immediate reward $r_{t+1}$ and the estimated value of $Q_{(s',a')}$ for next state $s' = s_{t+1}$:

$$p(s_t, a_t) \leftarrow p(s_t, a_t) + k(r_{t+1} + \max_{a'} Q(s_{t+1}, a')).$$  \hspace{1cm} (12)$$

where $k$ ($k \geq 0$) is an updating step size and the probability distribution of actions at state $s = s_t$ is normalized after each updating. The parameter setting of $k$ is accomplished by experience and generally can be set as the same as the learning rate $\alpha_t$. The variation of $k$ in a relatively large range will only slightly affect the learning process because the probability distribution $\{p(s, a_1), p(s, a_2), \ldots, p(s, a_m)\}$ is normalized after each updating step. In particular, $k$ is set as 0.01 for all the experiments in this paper.

The evolution of the probability distribution of action selection on the state-action space during the whole learning process is shown in Fig. 3, where the values of the action selection probabilities are represented with different colors. The probability distribution usually starts with an initial uniform one before learning (as shown in Fig. 3(1)), i.e., for each state $s$ the probability distribution of action selection is initialized as $\{p(s, a_i) = \frac{1}{m}, i = 1, 2, \ldots, m\}$. It evolves with the learning and probability updating process (a sample of the probability distribution during the learning process is shown in Fig. 3(2)) and reaches an optimal one when the learning process ends (Fig. 3(3)). Then the learned policy is applied to the agent (or a control system) and at the same time the learning system may still keep on-line learning capability. If the environment changes the probability distribution will be updated accordingly (Fig. 3(4)) and naturally trigger a re-learning process for the learning system. Fig. 3(5) and Fig. 3(6) show the process of re-learning for a new environment. The characteristics of the proposed probabilistic exploration strategy (as shown in Fig. 3) is very different from the traditional one, e.g., the $\epsilon$-greedy method for Q-learning, where action probability distribution for a certain state keeps constant as shown in Fig. 1(a).

Remark 1: The tradeoff between exploration and exploitation is a specific challenge of RL. Compared with existing exploration strategies, such as $\epsilon$-greedy, Softmax and simulated annealing methods, the probabilistic exploration strategy has the following merits. (i) The learning algorithm possesses more reasonable credit assignment using a probabilistic method and the action selection method is more natural without too much difficulty for parameter setting. The only parameter to be set is the step size $k$. The parameter $k$ will not substantially affect the algorithm performance, because the action selection probabilities for a certain state are relative and will be normalized after each updating step. (ii) The method provides a natural re-exploring mechanism (as shown in Fig. 3), i.e., when the environment changes, the policy also changes along with the on-line learning process. Such a re-exploring mechanism is difficult to implement for the existing exploration strategies (e.g., $\epsilon$-greedy). For example, the value of $\epsilon$ is usually decreased along with the learning process to exploit more after a lot of trials. When the environment changes the value of $\epsilon$ should be reset to avoid too much exploitation. However, it is difficult to do so intelligently. Our scheme provides a straightforward and natural approach for re-exploring mechanism. Although it may need a little bit more physical memories for probability distribution updating, it will not substantially degrade the algorithm, while the performance improvement is more prominent.

### B. Probabilistic Q-learning Algorithms

The procedural form of a probabilistic Q-learning algorithm is presented as Algorithm 1. In this PQL algorithm, after initializing the state and action we can choose $a_t$ according to the action probability distribution at state $s_t = s$. Execute this action and the system can give the next state $s_{t+1} = s'$, immediate reward $r_{t+1}$ and the estimated next-state-action function value $Q(s_{t+1}, a')$. $Q(s_t, a_t)$ is updated by the one-step Q-learning rule. The updating of $p(s_t, a_t)$ (the probability of choosing $a_t$ at state $s_t$) is also carried out based on $r_{t+1}$ and $Q(s_{t+1}, a')$. Hence, in the PQL algorithm, the exploration policy is accomplished through a probability distribution over the action set for each state. When the agent chooses an action at a certain state $s$, the action $a_t$ will be selected with probability $p(s, a_t)$ which is also updated along with the value function updating.

Compared with basic Q-learning algorithms, the main feature of the PQL algorithm is the straightforward probabilistic exploration strategy and the reinforcement strategy is also applied to dynamically update the probability distribution of action selection. The agent selects actions based on the variable probability distribution over an admissible action set at a certain state. Such an action selection method keeps a proper chance of exploration instead of obeying the policy learned so far, and makes a good tradeoff between exploration and exploitation using probability.
other complex RL problems. The control of quantum systems, which can also be applied to some widely used in quantum information community [19], [39], control problems are complex and the concept of fidelity is performance can be further improved for complex learning.

Hence, if we can extract more information during the learning process unless the agent reaches the objective is always delayed due to the lack of feedback information. For reinforcement learning problems, the direction of achieving the stochastic learning and optimization. But for most complex C. Fidelity-based PQL Algorithm

PQL uses a probabilistic action selection method to improve the exploration strategy and is an effective approach for stochastic learning and optimization. But for most complex reinforcement learning problems, the direction of achieving the objective is always delayed due to the lack of feedback information during the learning process unless the agent reaches the target state. Hence, if we can extract more information from the system structure or system behavior, the learning performance can be further improved for complex learning problems with large learning space. Because most of quantum control problems are complex and the concept of fidelity is widely used in quantum information community [19], [39], [40], we develop a fidelity-based PQL method for learning control of quantum systems, which can also be applied to some other complex RL problems.

The updating rule of fidelity-based PQL for $Q(s, a)$ is the same as (11). The probability distribution is updated for each learning step. After the execution of action $a_t$ for state $s = s_t$, the corresponding probability $p(s_t, a_t)$ is updated according to the immediate reward $r_{t+1}$, the estimated value of $Q(s_{t+1}, a')$ for next state $s' = s_{t+1}$ and the fidelity $F(s_{t+1}, s_{\text{target}})$ between the state $s_{t+1}$ and the target state $s_{\text{target}}$. That is

$$p(s_t, a_t) \leftarrow p(s_t, a_t) + k(r_{t+1} + \max_{a'} Q(s_{t+1}, a') + F(s_{t+1}, s_{\text{target}}))$$

(13)

The specification of the fidelity $F(s_{t+1}, s_{\text{target}})$ is defined regarding the objective of the learning control task. In this study, a fidelity of quantum pure states (see Subsection IV-A) is adopted for the learning control of quantum systems. The parameter setting methods and the normalization of the probability distribution of actions at state $s = s_t$ are the same as that of PQL. The procedure of the fidelity-based PQL algorithm is shown as Algorithm 2.

Algorithm 1 Probabilistic Q-learning

1: Initialize $Q(s, a)$ arbitrarily
2: Initialize the policy $\pi: P^\pi = (p^\pi(s, a))_{n \times m}$ to be evaluated
3: repeat (for each episode)
4: Initialize $t = 1, s_t$
5: repeat (for each step of episode)
6: $a_t \leftarrow$ action $a_t$ with probability $p(s_t, a_t)$ for $s_t$
7: Take action $a_t$, observe reward $r_{t+1}$, and next state $s_{t+1}$
8: $Q(s_t, a_t) \leftarrow Q(s_t, a_t) + \alpha \delta^Q_{t+1}$
9: where $\delta^Q_{t+1} = r_{t+1} + \gamma \max_{a'} Q(s_{t+1}, a') - Q(s_t, a_t)$
10: $p(s_t, a_t) \leftarrow p(s_t, a_t) + k(r_{t+1} + \max_{a'} Q(s_{t+1}, a'))$
11: Normalize $\{p(s_i, a_i)|i=1,2,...,m\}$
12: $t \leftarrow t + 1$
13: until $s_{t+1}$ is terminal
14: until the learning process ends

Algorithm 2 Fidelity-based Probabilistic Q-learning

1: Initialize $Q(s, a)$ arbitrarily
2: Initialize the policy $\pi: P^\pi = (p^\pi(s, a))_{n \times m}$ to be evaluated
3: repeat (for each episode)
4: Initialize $t = 1, s_t$
5: repeat (for each step of episode)
6: $a_t \leftarrow$ action $a_t$ with probability $p(s_t, a_t)$ for $s_t$
7: Take action $a_t$, observe reward $r_{t+1}$, and next state $s_{t+1}$
8: $Q(s_t, a_t) \leftarrow Q(s_t, a_t) + \alpha \delta^Q_{t+1}$
9: where $\delta^Q_{t+1} = r_{t+1} + \gamma \max_{a'} Q(s_{t+1}, a') - Q(s_t, a_t)$
10: $p(s_t, a_t) \leftarrow p(s_t, a_t) + k(r_{t+1} + \max_{a'} Q(s_{t+1}, a')) + F(s_{t+1}, s_{\text{target}})$
11: where $\delta^F_{t+1} = r_{t+1} + \max_{a'} Q(s_{t+1}, a') + F(s_{t+1}, s_{\text{target}})$
12: Normalize $\{p(s_t, a_t)|i=1,2,...,m\}$
13: $t \leftarrow t + 1$
14: until $s_{t+1}$ is terminal
15: until the learning process ends

As for the convergence of FPQL, it is the same as that of basic Q-learning [3], because the difference only lies in the exploration policy which does not affect the convergence of the algorithms. Several constraints [3], [43] are listed in Theorem 1 to ensure the convergence of FPQL.

Theorem 1 (Convergence of FPQL): Consider an FPQL agent in a nondeterministic Markov decision process, for every
state-action pair \( s \) and \( a \), the Q-value \( Q_t(s, a) \) will converge to the optimal state-action value function \( Q^*(s, a) \) if the following constraints are satisfied

1) The rewards in the whole learning process satisfy \( (r(s, a))^2 \leq R \), where \( R \) is a finite constant value;
2) A discount factor \( \gamma \in [0, 1) \) is adopted;
3) During the learning process, the nonnegative learning rate \( \alpha_t \) satisfies

\[
\lim_{T \to \infty} \sum_{t=1}^{T} \alpha_t = \infty, \quad \lim_{T \to \infty} \sum_{t=1}^{T} \alpha_t^2 < \infty. \tag{14}
\]

The difference between the proposed fidelity-based probabilistic exploration strategy and the existing exploration strategies can be explained from a point of view of physical mechanism. As shown in Fig. 4, for a learning optimization problem, the existing exploration strategies, e.g., \( \epsilon \)-greedy, softmax and simulated annealing methods, apply a thermal fluctuation type of exploration methods to acquire the chance of stepping over the local optima; while the probabilistic exploration strategy is inspired by quantum phenomena. It behaves like quantum tunnelling effect and can step over the local optima in a more straightforward way. The direction of the fidelity can strengthen this tunnelling effect. The physical explanation can help demonstrate why the fidelity-based probabilistic method may perform better for complex reinforcement learning tasks.

**Remark 2:** Although the fidelity-based PQL method is proposed for learning control of quantum systems, it can also be applied to other RL problems when there is a clear and quantitative definition of fidelity that can effectively characterize the distance between the current state and the target state. The fidelity information can speed up the learning process in that it shows the direction to the target state and can help the learning process get out of the traps when get lost. In addition, this fidelity signal is only used to regulate the action selection probability distribution. It will not deteriorate the exploration strategy of PQL.

**Remark 3:** It is clear that the optimal policy of FPQL is also the process of reducing the uncertainty of decisions on which action should be chosen at a state. Hence, the characteristics of the FPQL algorithm and its performance can also be described with the degree of uncertainty for action selection. The measurement of uncertainty has been well addressed through **Shannon entropy** (i.e., Shannon measure of uncertainty) \[44\] in information science, where the amount of uncertainty is measured by a probability distribution function \( p \) on a finite set: \( S(p) = -\sum_{x \in X} p(x) \log_2 p(x) \), where \( X \) is the element of the finite set \( X \) and \( p(x) \) is the probability distribution function on \( X \). Similar to Shannon entropy, the concept of **Exploration Entropy** can also be given based on the probability distributions of actions to measure the uncertainty of action selection. The resulting function is \( E_s = -\sum P(a|s) \log_2 P(a|s) \). For an FPQL system, the general uncertainty of action selection can be described with the mean exploration entropy \( \overline{E}_s = \frac{1}{n} \sum_{i=1}^{n} E_{si} \), where \( S = \{s_1, s_2, ..., s_n\} \) is the state set. It is clear that when all the probabilities are equal the exploration entropy (uncertainty of action selection) will be maximum. In an FPQL system, the maximum exploration entropy of a state \( s \) with \( m \) actions will be \( \log_2 m \). The maximum mean decision entropy \( \overline{E}_s \) should be obtained when all the action probability distributions for each state are uniform, which is always the situation at the initialization without any prior knowledge about the environment. Along with the learning process, \( \overline{E}_s \) will tend to decrease and obtain its minimum when the learning process converges and gives the optimal policy.

IV. FIDELITY-BASED PQL FOR LEARNING CONTROL OF QUANTUM SYSTEMS

**A. Learning control of quantum systems**

Learning control is an effective method for quantum systems where a control law can be learned from experience and the system performance can be optimized by searching for an optimal control strategy in an iterative way \[21\], \[45\]-\[47\]. Here, we focus on the control problem of quantum pure state transition for \( N \)-level quantum systems \[38\]. Denote the eigenstates of the free Hamiltonian \( H_0 \) of an \( N \)-level quantum system as \( D = \{|\phi_i\rangle\}_{i=1}^{N} \). An evolving state \( |\psi(t)\rangle \) of the controlled system can be expanded in terms of the eigenstates in the set \( D \):

\[
|\psi(t)\rangle = \sum_{i=1}^{N} c_i(t) |\phi_i\rangle \tag{15}
\]

where complex numbers \( c_i(t) \) satisfy \( \sum_{i=1}^{N} |c_i(t)|^2 = 1 \). We have the definition of fidelity between two pure states.

**Definition 2 (Fidelity of Quantum Pure States):** The fidelity between two pure states \( |\psi^a\rangle = \sum_{i=1}^{N} c_i^a |\phi_i\rangle \) and \( |\psi^b\rangle = \sum_{i=1}^{N} c_i^b |\phi_i\rangle \) is defined as

\[
F(|\psi^a\rangle, |\psi^b\rangle) = \langle |\psi^a\rangle |\psi^b\rangle = \sum_{i=1}^{N} (c_i^a)^* c_i^b, \tag{16}
\]

where \((c_i^a)^*\) is the complex conjugate of \( c_i^a \).

Introducing a control \( \varepsilon(t) \in L^2(\mathbb{R}) \) acting on the system via a time-independent interaction Hamiltonian \( H_I \) and denoting
\[ |\psi(t = 0)\rangle \text{ as } |\psi_0\rangle, C(t) = (c_i(t))_{i=1}^N \text{ evolves according to the Schrödinger equation } \text{[32]}. \]

\[
\begin{align*}
\text{d}t \hat{C}(t) &= [A + \varepsilon(t)B]C(t) \\
C(t = 0) &= C_0 
\end{align*}
\tag{17}
\]

where \( t = \sqrt{-1}, C_0 = (c_0)_{i=1}^N, c_0i = \langle \phi_i | \psi_0 \rangle, \sum_{i=1}^N |c_0|^2 = 1, \hbar \) is the reduced Planck constant, and the matrices \( A \) and \( B \) correspond to \( H_0 \) and \( H_1 \), respectively. We assume that the \( A \) matrix is diagonal and the \( B \) matrix is Hermitian \([32]\). In order to avoid trivial control problems we assume \([A, B] \equiv AB - BA \neq 0\). Equation (17) describes the evolution of a finite dimensional control system. The propagator \( U(t_1 \rightarrow t_2) \) is a unitary operator such that for any state \( |\psi(t_1)\rangle \) the state \( |\psi(t_2)\rangle = U(t_1 \rightarrow t_2)|\psi(t_1)\rangle \) is the solution at time \( t = t_2 \) of (13) and (17) with the initial condition \( |\psi(t_1)\rangle \) at time \( t = t_1 \). \( U(t_1 \rightarrow t_2) \) is also simplified as \( U(t) \), \( t \in [t_1, t_2] \), if the specific time \( t_1 \) can be neglected when handling these problems. Assume that the control set \( \{\varepsilon_j, j = 1, \ldots, m\} \) is given. Every control \( \varepsilon_j \) corresponds to a unitary operator \( U_j \). The task of learning control is to find a control sequence \( \{\varepsilon_l, l = 1, 2, 3, \ldots\} \) with \( \varepsilon_l \in \{\varepsilon_j, j = 1, \ldots, m\} \) to drive the quantum system from an initial state \( |\psi_0\rangle \) to the target state \( |\psi_f\rangle \).

**Remark 4:** In the past decade, the research areas of quantum information and machine learning have mutually benefitted from each other. On one hand, quantum characteristics have been used for designing quantum or quantum-inspired learning algorithms \([18], [19], [43], [52]\). On the other hand, many traditional learning algorithms have been applied for the control design of quantum phenomena, including gradient-based algorithms \([42], [53]\), genetic algorithm (GA) \([45], [54]\), and fuzzy logic \([38]\). For example, gradient-based methods have been widely used in model-based control design and theoretical analysis of quantum systems. Since we assume that very limited control resources are available, gradient-based algorithms cannot be applied to the quantum control problem in this paper. GA methods have achieved great success for quantum learning control in laboratory \([45]\). However, a large amount of experimental data is required to optimize the control performance since the closed-loop learning process involves the collection of experimental data and the searching of optimized pulses based on the updating of experimental data \([45]\).

In this paper, we consider a class of quantum control problems with a limited set of control fields. This class of problems is significant in quantum control since different constraints are common for quantum control systems. We formulate this class of quantum control problems as a model-free sequential Markovian decision process (MDP). Reinforcement learning is a good candidate to solve a MDP problem. Hence, we apply the proposed FPQL approach to this class of quantum control problems that can be used to test the effectiveness of FPQL as well as to provide an effective design approach for quantum systems with limited control resources.

**B. Quantum controlled transition landscapes**

Learning control of quantum systems aims to find an optimal control strategy to manipulate the dynamics of physical processes on the atomic and molecular scales \([45]\). In recent years, quantum control landscapes \([41], [42]\) provide a theoretical footing for analyzing learning control of quantum systems. A control landscape is defined as the map between the time-dependent control Hamiltonian and associated values of the control performance functional. Most quantum control problems can be formulated as the maximization of an objective performance function. For example, as shown in Fig. 5, the performance function \( J(\varepsilon) \) is defined as the functional of the control strategy \( \varepsilon \) at \( t = \varepsilon \), with \( t = 1, 2, ..., M \), where \( M \) is a positive integer that indicates the number of the control variables \( (M = 2 \text{ for the case shown in Fig. 5}) \).

Although quantum control applications may span a variety of objectives, most of them correspond to maximizing the probability of transition from an initial state \( |\psi_0\rangle \) to a desired final state \( |\psi_f\rangle \) \([41]\). For the state transition problem with \( t \in [0, T] \), we define the quantum controlled transition landscape as

\[
J(\varepsilon) = \text{tr}(U(\varepsilon, T)|\psi_0\rangle\langle\psi_0|U(\varepsilon, T)^\dagger|\psi_f\rangle\langle\psi_f|),
\tag{18}
\]

where \( \text{tr}(\cdot) \) is the trace operator and \( U^\dagger \) is the adjoint of \( U \). The objective of the learning control system is to find a global optimal control strategy \( \varepsilon^* \) which satisfies

\[
\varepsilon^* = \arg\max_{\varepsilon} J(\varepsilon). \tag{19}
\]

If the dependence of \( U(\varepsilon, T) \) on \( \varepsilon \) is suppressed (see \([42]\), \([18]\) can be reformulated as

\[
J(U) = \text{tr}(U(\varepsilon, T)|\psi_0\rangle\langle\psi_0|U(\varepsilon, T)^\dagger|\psi_f\rangle\langle\psi_f|),
\tag{20}
\]

Equations (18) and (20) are called the dynamic control landscape (denoted as \( J_D(\varepsilon) \) instead) and the kinematic landscape.
(denoted as \(J_K(U)\) instead), respectively (see [42]).

The characteristic of the existence or absence of traps is most important for exploring the quantum control landscape with a learning control algorithm, which can be studied using critical points. A dynamic critical point is defined by

\[
\nabla J_D(\varepsilon) = \frac{\partial J_D(\varepsilon)}{\partial \varepsilon} = 0
\]

and a kinematic critical point is defined by

\[
\nabla J_K(U) = \frac{\partial J_K(U)}{\partial U} = 0
\]

where \(\nabla\) denotes gradient. By the chain rule, we have

\[
\nabla J_D(\varepsilon) = \frac{\partial J_K(U)}{\partial U} \frac{\partial U}{\partial \varepsilon} = \nabla J_K(U) \frac{\partial U}{\partial \varepsilon}.
\]

According to the results in [42], we can summarize the properties of quantum controlled transition landscape as Theorem 2.

**Theorem 2:** For the quantum control problem defined with the dynamic control landscape [18] and the kinematic control landscape [20], respectively, the properties of the solution sets of the quantum controlled transition landscape are listed as follows:

1) The kinematic control landscape is free of traps (i.e., all critical points of \(J_K(U)\) are either global maxima or saddles) if the operator \(U\) can be any unitary operator (i.e., the system is completely controllable);

2) The dynamic control landscape is free of traps if (i) the operator \(U\) can be any unitary operator and (ii) the Jacobian \(\frac{\partial U(\varepsilon, T)}{\partial \varepsilon}\) has full rank at any \(\varepsilon\).

For detailed proof and discussion about Theorem 2 please refer to [41], [42].

**Remark 5:** The quantum controlled transition landscape theory is the theoretical foundation for learning control design. The FPQL algorithm has potential for quantum learning control problems. The reasons can be stated from three aspects: (i) The probabilistic action selection method makes a better balance between exploration and exploitation, since too much exploitation is easy to be trapped and too much exploration will deteriorate the learning performance; (ii) The theoretical analysis of the solution sets of a quantum control landscape can help design a fidelity-based method to improve the learning performance; (iii) The learning scheme of reinforcement learning is more suitable for model-free real laboratory applications than typical gradient-based methods which need specific models.

In the next two subsections, the learning control problems of a spin-\(\frac{1}{2}\) system and a \(\Lambda\)-type atomic system are studied using the proposed FPQL algorithm, which shows that FPQL is an alternative effective approach for quantum control design.

**C. Example 1: learning control of a spin-\(\frac{1}{2}\) quantum system**

The spin-\(\frac{1}{2}\) system is a typical 2-level quantum system and has important theoretical implications and practical applications. Its Bloch vector can be visualized on a 3D Bloch sphere as shown in Fig. 6. The state of the spin-\(\frac{1}{2}\) quantum system \(|\psi\rangle\) can be represented as

\[
|\psi\rangle = \cos \frac{\theta}{2} |0\rangle + e^{i\varphi} \sin \frac{\theta}{2} |1\rangle
\]

where \(\theta \in [0, \pi]\) and \(\varphi \in [0, 2\pi]\) are polar angle and azimuthal angle, respectively, which specify a point \(\mathbf{r} = (x, y, z) = (\sin \theta \cos \varphi, \sin \theta \sin \varphi, \cos \theta)\) on the unit sphere in \(\mathbb{R}^3\).

At each control step, the permitted controls for every state are \(U_1\) (no control input), \(U_2\) (a positive pulse control) and \(U_3\) (a negative pulse control). Fig. 6 shows a sketch map of one-step control effects on the evolution of the quantum system. The propagators \(\{U_i, i = 1, 2, 3\}\) are listed as follow:

\[
U_1 = e^{-i\frac{I_z}{2} \frac{\varphi}{2}}, \quad U_2 = e^{-i\frac{I_z+0.5I_x}{2} \frac{\varphi}{2}}, \quad U_3 = e^{-i\frac{I_z-0.5I_x}{2} \frac{\varphi}{2}}.
\]

where

\[
I_z = \frac{1}{2} \begin{pmatrix} 1 & 0 & 0 \\ 0 & 0 & -1 \\ 0 & 1 & 0 \end{pmatrix}, \quad I_x = \frac{1}{2} \begin{pmatrix} 0 & 1 & 0 \\ 1 & 0 & 0 \end{pmatrix}.
\]

Now the control objective is to control the spin-\(\frac{1}{2}\) system from the initial state \((\theta = \frac{\pi}{6}, \varphi = \frac{\pi}{3})\) to the target state \((\theta = \frac{3\pi}{6}, \varphi = \frac{5\pi}{6})\) with minimized control steps. Fig. 7 shows one of the control process before learning, where the controls are selected randomly and after a long control sequence the system may be transited to the target state. We apply the fidelity-based PQL, PQL and QL algorithms to this learning control problem, respectively. Now we reformulate the RL problem of controlling a quantum system from an initial state \(s_{\text{initial}} = |\psi_{\text{initial}}\rangle\) to a desired target state \(s_{\text{target}} = |\psi_{\text{target}}\rangle\) as follows: the state set is \(S = \{|s_i\rangle, i = 1, 2, \ldots, n\}\) and the
settings for these algorithms are listed as follows: $r = -1$ for each control step until it reaches the target state, then it gets a reward of $r = 1000$; the discount factor $\gamma = 0.99$, the learning rate $\alpha = 0.01$ and the Q-values are all initialized as 0. For PQL and fidelity-based PQL, $k = 0.01$. The $\epsilon$-greedy exploration strategy is used and $\epsilon = 0.1$.

Actions set is $A = \{a_j = u_j\}, j = 1, 2, \ldots, m$. The experiment settings for these algorithms are listed as follows: $r = -1$ for each control step until it reaches the target state, then it gets a reward of $r = 1000$; the discount factor $\gamma = 0.99$, the learning rate $\alpha = 0.01$ and the Q-values are all initialized as 0. For PQL and fidelity-based PQL, $k = 0.01$. The $\epsilon$-greedy exploration strategy is used and $\epsilon = 0.1$.

Figs. 8-10 show the control performance of all these algorithms, respectively. Hundreds of times of learning process are carried out for each experiment and all the results maintain similar performance. We provide the results of one time of learning process for each experiment. The experimental results show that fidelity-based PQL outperforms PQL and standard QL. The fidelity-based PQL quickly finds the optimal control sequence after less than 50 episodes, while PQL needs about 150 episodes and QL needs more than 200 episodes. For each episode in the learning process, QL and PQL also need much more steps to find the target state. A clearer performance comparison between the fidelity-based PQL, PQL and QL is shown as in Fig. 11. It is clear that the fidelity-based method contributes to more effective tradeoff between exploration and exploitation than PQL and confines it from exploring too much in an economical way with respect to exploration cost. Although the fidelity-based PQL needs a little more steps in the early learning stage (which makes its performance lies between QL and PQL), it can quickly converge to the optimal policy and remarkably outperforms both of QL and PQL. The final control results with the learned optimal control sequence that controls the spin-$\frac{1}{2}$ quantum state from the initial state to the target state is demonstrated in Fig. 12.

D. Example 2: learning control of a $\Lambda$-type quantum system

Now we consider a $\Lambda$-type atomic system and demonstrate the fidelity-based PQL design process. The three level $\Lambda$-type atomic system is a representative of the multi-level system, which has wide applications in the fields of chemistry, quantum physics and quantum information [55]. For the $\Lambda$-type system shown in Fig. 13, the evolving state $|\psi(t)\rangle$ can be expanded in terms of the eigenstates as follows:

$$|\psi(t)\rangle = c_1(t)|1\rangle + c_2(t)|2\rangle + c_3(t)|3\rangle,$$  \hspace{1cm} (29)

where $|1\rangle$, $|2\rangle$ and $|3\rangle$ are the basis states of the lower, middle and upper atomic states, respectively. At each control step, the permitted controls are a finite number of (positive or negative) control pulses, i.e., we have the propagators

$$U_E = e^{-i\Delta t(H_0 + \epsilon EH_1)}$$  \hspace{1cm} (30)

where $\Delta t = 0.1$,

$$H_0 = \begin{pmatrix} 1.5 & 0 & 0 \\ 0 & 1 & 0 \\ 0 & 0 & 0 \end{pmatrix}, \quad H_1 = \begin{pmatrix} 0 & 0 & 1 \\ 0 & 0 & 1 \\ 1 & 1 & 0 \end{pmatrix},$$  \hspace{1cm} (31)

and $E \in \{0, \pm 1, \pm 2, \ldots, \pm 20\}$ is the number of chosen control pulses at a certain control step.

Now the control objective is to control the $\Lambda$-type atomic system from the initial state $|\psi_{\text{initial}}\rangle = (1, 0, 0)$ to the target state $|\psi_{\text{target}}\rangle = (0, 0, 1)$ with a fixed number of control steps. We apply the fidelity-based PQL, PQL and QL algorithms to this learning control problem, respectively. First we reformulate the RL problem of controlling a quantum system from an initial state $s_{\text{initial}} = |\psi_{\text{initial}}\rangle$ to a desired target state $s_{\text{target}} = |\psi_{\text{target}}\rangle$ as follows: the number of control steps is fixed...
Fig. 8. Learning performance of fidelity-based PQL and the learning results with an optimal control sequence

Fig. 9. Learning performance of PQL and the learning results with an optimal control sequence

Fig. 10. Learning performance of standard QL with $\varepsilon$-greedy policy and the learning results with an optimal control sequence
as a constant number of 100, so that we can use a virtual state set to construct the state-action space instead of the real state space (with a very high dimension) of the Λ-type system and the state set \( S = \{ s_i \}, i = 1, 2, \ldots, 101 \) and the action set is \( A = \{ a_j = E_j = j - 21 \}, j = 1, 2, \ldots, 41 \). The experiment settings for these algorithms are listed as follows: \( r = 0 \) for each control step until it reaches the target state at the end of the control process where it gets a reward of \( r = 1000 \); the discount factor \( \gamma = 0.99 \), the learning rate \( \alpha = 0.01 \) and the Q-values are all initialized as 0. For PQL and fidelity-based PQL, \( k = 0.01 \). The \( \epsilon \)-greedy exploration strategy is used for QL and \( \epsilon = 0.1 \). The fidelity for a current policy \( \pi \) is defined as \( F = |\langle \psi^f | \psi_{\text{target}} \rangle| \).

The learning performances of fidelity-based PQL, PQL and QL are shown in Fig. 14 with respect to fidelity, which is one of all the alike results for hundreds of experiments we carried out. The learning process converges after about 300 episodes using fidelity-based PQL, while PQL needs about 1450 episodes and QL needs about 2000 episodes. The oscillation for PQL and QL before the learning processes converge in Fig. 14 is due to the performance criteria regarding fidelity instead of accumulated learning steps as used in Fig. 11. The performance shown in Fig. 14 is very sensitive to the exploration behavior in the state-action space for PQL and QL, while the fidelity-based method shows an almost monotonically improved learning behavior.

The final optimal control sequence is shown in Fig. 15. With this learned optimal control sequence the Λ-type atomic system described by Equations (29)-(31) is controlled from the initial state \( |\psi_{\text{initial}}\rangle = (1, 0, 0) \) to the target state \( |\psi_{\text{target}}\rangle = (0, 0, 1) \) and the population evolution trajectories are demonstrated in Fig. 16. All these numerical results demonstrate the
success of the proposed fidelity-based PQL method. In addition, the learning control of the Λ-type atomic system can also be implemented with policy iteration [9, 10], but it is out of the scope of this paper. More comparison results between the value iteration and policy iteration for reinforcement learning will be presented in our future work.

V. CONCLUSIONS

In this paper, a probabilistic action selection method is introduced for Q-learning and an FPQL algorithm is presented for the learning control design of quantum systems. In FPQL, the fidelity information can be extracted from the system structure or the system behavior. The aim is to design a good exploration strategy for a better tradeoff between exploration and exploitation and to speed up the learning process as well. The experimental results show that FPQL is superior to basic Q-learning with respect to convergence speed. The control problems of a spin- system and a Λ-type atomic system are adopted to demonstrate the performance of FPQL. Although all the cases we considered in this study are discrete examples, which are most widely used in practical applications, the proposed fidelity-based probabilistic action selection method can be extended to other reinforcement learning algorithms and applications using function approximation with a continuous probability distribution and related iteration methods. In addition, our future work will focus on further comparison of FPQL with other existing learning methods (e.g., GA, gradient-base methods and neural networks) for more general quantum control problems.
