The emerging role of fibrocytes in ocular disorders

Feng Zhang1,2, Ke Liu1,2, Han Zhao1,2 and Yan He1,2*

Abstract
The fibrocyte, which was first described in 1994, is a type of circulating mesenchymal progenitor cell in the peripheral blood. Fibrocytes play important roles in chronic inflammation, wound healing, tissue remodeling, and fibrosis. Emerging evidence indicates that fibrocytes are involved in a wide variety of ocular disorders associated with inflammation and fibrosis. In this review, we summarize recent advances regarding the general characteristic profile of fibrocytes, molecular mechanisms underlying the fibrocyte recruitment to target tissues, their differentiation into fibroblasts, and the potential role of fibrocytes in ocular disease. Given the critical role of fibrocytes in ocular disorders, fibrocytes may serve as a promising pharmaceutical target in the development of novel therapeutic strategies to treat ocular inflammation and fibrosis.

Keywords: Fibrocytes, Mesenchymal progenitor cell, Fibrosis, Inflammation, Ocular disorders

Background
Adult bone marrow contains a large number of distinct stem or progenitor cells, including hematopoietic stem cells, mesenchymal stem cells, endothelial progenitor cells, and fibrocytes. It has been suggested that other progenitor cells, as well as hematopoietic stem cells, could be involved in the process of hematopoiesis support, neovascularization, and tissue regeneration or wound healing, supporting the blood cells [1–3]. Fibrocytes are among these other progenitor cells, with the features of both lymphocytes and fibroblasts, that have become increasingly researched recently. Circulating fibrocytes were first identified in 1994 in an in vivo study using an animal model of wound repair and were defined by their unique co-expression of hematopoietic and progenitor cell markers (CD45 and CD34, respectively), together with the production of extracellular matrix (ECM) [4]. In addition, fibrocytes express a number of chemokine receptors and adhesion molecules, some of which are critical for the recruitment of fibrocytes to sites of tissue injury, fibrosis, and inflammation [5–7].

Due to the properties of mesenchymal stem cells, fibrocytes are capable of differentiating into several cell lineages, such as classic trilineage cells (including adipocytes, osteoblasts, and chondrocytes), fibroblasts, and myofibroblasts [8, 9]. The function of these cells has been shown to be involved in several pathological processes encompassing fibrosis, inflammation, neovascularization, and some immunological diseases. A large number of in vitro and in vivo studies have revealed distinct roles of fibrocytes in a wide variety of ocular disorders. In this review, we will focus on the latest advances regarding the emerging roles of fibrocytes in ocular disease and the therapeutic potential of specific treatments targeting fibrocytes.

Origin and phenotypic characteristics
The term fibrocyte, which combines the term fibroblast with leukocyte, thrombocyte, and erythrocyte, was coined for the peripheral blood circulating fibroblast progenitor that produces collagen and also expresses the hematopoietic marker CD34 [10]. Since there are various studies that have focused on fibrocytes involved in diverse pathogeneses, including fibrosis and inflammation, different views of the origin of fibrocytes have arisen. In 1994, Bucala and his colleagues first described a subpopulation of spindle-shaped adherent cells that expressed collagen, CD34, and CD45. They named these cells “fibrocytes”, which represented about 10% of the whole cell population in the wound chamber [4].

Fibrocytes constitute 0.1–0.5% of circulating non-erythrocytes and were isolated from the peripheral blood monocytes [4, 11]. Thus, historically, it was believed that fibrocytes were one type of monocyte in the peripheral
blood. However, emerging evidence indicates that fibrocytes are more likely to be originally derived from monocytes [12–14]. Their presumed monocyte origin is proved by the expression of CD11b and CD11c. Interestingly, monocytes consisting of a mixed population of progenitors likely replenish the tissue-resident macrophage and dendritic cell populations in the absence of inflammation after an initial differentiation into different subtypes of monocytes before they enter the tissues. During inflammatory processes, however, a population of monocytes directly migrates to inflamed sites, predominantly through a CCR2-mediated signaling pathway, and differentiate into fibrocytes as a player in inflammation and tissue repair [15, 16]. There are several distinct regulators involved in the process of fibrocytes differentiation. An animal study revealed that differentiation of fibrocytes is critically dependent on CD4⁺ T cells and T-cell activation, which determines whether the development of fibrocytes is supported or blocked [17]. Cytokines produced by Th1 and Th2 cells, respectively (such as interleukin (IL)-4, IL-13, IL-2, and tumor necrosis factor (TNF)), inhibit or promote fibrocyte fate [18, 19]. In serum-free media, some peripheral blood monocytes differentiated into fibrocytes within 5 days, and such differentiation was inhibited by the blood plasma protein serum amyloid P (SAP) [13] likely through its interaction with FcγRI [20]. Other factors affecting fibrocyte differentiation include hyaluronic acids and CD44. High molecular weight hyaluronic acid (HWMHA) potentiates the differentiation of human monocytes to fibrocytes and, in contrast, low molecular weight hyaluronic acid (LWMHA) inhibits fibrocyte differentiation. CD44 may be involved in the regulation of the process of fibrocyte differentiation, with a dominance hierarchy of SAP > LMWHA > HMWHA > IL-4 or IL-13 [21]. The number of circulating fibrocytes was not decreased when a monoclonal antibody against CCR2 was used to deplete monocytes in a mouse model, suggesting that fibrocytes develop outside the kidney independent of infiltrating monocytes and rely on CCR2 for migration into target organs.

Circulating fibrocytes, a slender spindle-shaped cell type (Fig. 1), exhibit several phenotypic characteristics attributed to the variety of their properties. Consistent with their bone marrow or hematopoietic origin, fibrocytes express CD45, leukocyte-specific protein-1 (LSP-1), and CD34 (a hematopoietic progenitor marker) [22]. Although fibrocytes produce collagen or ECM they were not discovered until the early 1990s. This is likely due to an underestimation of fibrocyte counts as they progressively lose CD34 and CD45 [23]. Moreover, collagen could be a noisy marker to discriminate between other lineages because of its overlap expression by fibroblasts or macrophages [24]. To address this confusion, Pilling et al. screened fibrocytes, monocytes, and macrophages with commercially available reagents to identify markers that could accurately discriminate between these populations, together with their different morphology [24]. One of their principal findings was that only fibrocytes (50–200 μm long spindle-shaped cells with an oval nucleus) expressed CD45RO, 25F9, and S100A8/A9, but not PM-2 K, which could distinguish fibrocytes from other populations [24]. Some additional characteristics and markers of fibrocytes are summarized in Table 1. As mentioned above, there is currently no unified or specific standard for identifying fibrocytes. Fibrocytes have the characteristics of both macrophages and fibroblasts. To differentiate fibrocytes from macrophages and fibroblasts, positive staining of intracellular collagen, fibronectin and vimentin, the co-expression of specific markers (such as CD34, CD45, CXCR4), and the presence of at least several unique features indicated in Table 1 would be an appropriate criterion for defining fibrocytes. In addition, fibroblasts constitute the main resident cells of connective tissue and are considered in a state of activation. In fact, active fibroblast morphology is different from fibrocytes. Fibroblasts have a branched cytoplasm surrounding an elliptical, speckled nucleus (Fig. 2), and, in contrast, inactive fibrocytes are small and spindle-shaped.

**Proliferating and transforming cytokines of fibrocytes**

Several studies have identified a profibrotic lung phenotype in aging mice characterized by an increase in the number of fibroblasts lacking the expression of thymocyte differentiation antigen 1 (Thy-1) and an increase in transforming growth factor (TGF)-β1 expression [23, 25, 26]. These findings suggest that TGF-β1 epigenetically regulates the lung fibroblast phenotype through methylation of the Thy-1 promoter [24, 27, 28]. Targeted inhibition of DNMT
in the right clinical context might prevent fibroblasts from myofibroblast transdifferentiation and collagen deposition, which in turn could prevent fibrogenesis in the lung and other organs [21, 29]. However, the proliferation ability of fibrocytes in vitro is limited; they cannot proliferate indefinitely because of the Hayflick limit.

**Homing chemokines of fibrocytes (CXCL12/CXCR4)**

Fibrocytes can migrate to the site of injury and inflammation, mediated by various chemokine receptors (Table 1), and are able to produce numerous cytokines which take part in the process of inflammation or tissue remodeling. Once there, they differentiate into myofibrocytes and begin the process of tissue remodeling which ultimately culminates in fibrosis [6]. The pivotal CXCL12/CXCR4 axis in fibrocyte chemotaxis, which is implicated in the recruitment process of fibrocytes, has recently attracted attention [26, 30]. Both anti-CXCL12 antibody and direct CXCR4 antagonism have shown protective effects against the development of fibrosis by blocking the fibrocyte trafficking [27, 28].

Inhibition of the mammalian target of rapamycin (mTOR) pathway, a possible upstream factor of CXCL12/CXCR4, with rapamycin has been shown to effectively reduce the recruitment of fibrocytes into tracheal allografts.

### Table 1 Properties and markers used to identify fibrocytes (Continued)

| Property | Expression |
|----------|------------|
| Fibronectin, α-SMA | +/- |
| Collagen V | + |
| MMP-9 | ++ |
| Glycosaminoglycans | |
| Perlecan, versican, hyaluronan | ++/+ |
| Decorin, biglycan | + |
| Adhesion and motility markers | |
| CD43, CD164, galectin 3, LSP1 | +/+ |
| CD29, CD44, CD81, ICAM1, CD81 | + |
| Miscellaneous | |
| Semaphorin 7A | + |
| CD115 | - |
| CD90 | +/- |
| CD105 | + |
| CD70 | - |
| vWF | - |

The symbols represent high or increasing level of expression (+++, ++), conflicting reports or equivocal evidence of expression level (+/-), and no expression (-), and have been arbitrarily assigned to each marker based on published data [6, 7, 22]

α-SMA: α-smooth muscle actin, CCR: CC-chemokine receptor, CXCR: CXC-chemokine receptor, ECM: extracellular matrix, FAP: fibroblast activation protein, ICAM1: intercellular adhesion molecule 1, LSP1: leukocyte-specific protein-1, MCP-1: monocyte chemotactic protein 1, MMP: matrix metalloproteinase, TGF-β1: transforming growth factor-β1, vWF: Von Willebrand factor

### Table 1 Properties and markers used to identify fibrocytes

| Property | Expression |
|----------|------------|
| Functions | |
| Cytokine production | ++ |
| Immune cell trafficking | ++ |
| ECM production | ++ |
| α-SMA production | + |
| Lipid metabolism | + |
| Antigen presentation | ++ |
| Angiogenesis | + |
| MMP production | + |
| Chitinase production | + |
| Growth factors (TGF-β1, MCP-1) | +/++ |
| Monocyte markers | |
| CD11a, CD11b, CD11c, CD13, CD32, CD64 | +/- |
| CD14 | +/- |
| CD16 | - |
| Stem cell/progenitor markers | |
| CD34 | + |
| CD105 | + |
| Dendritic cell markers | |
| CD1a, CD10, CD83 | - |
| B cell markers | |
| CD19 | - |
| T cell markers | |
| CD3, CD4, CD8, CD25, CD56 | - |
| Macrophages markers | |
| CD45RO, 25F9, S100A8/A9 | + |
| PM-2 K | - |
| Integrins | |
| CD18, CD29, CD49b, CD49e, CD61 | ++ |
| CD49a | + |
| CD49c, CD49d, CD49f, CD103, α,β7 | - |
| Cell surface enzymes | |
| CD10, CD172a | + |
| prolyl14-hydroxylase | + |
| FAP | + |
| Scavenging receptors and molecules involved in host defense | |
| CD68, CD163, CD206, CD209, CD35, CD36 | +/- |
| Chemokine receptors | |
| CCR1, CCR2, CCR3, CCR4, CCR5, CCR7, CCR9, CXCR1, CXCR4, CX3CR1, CXCR3 | +/- |

| CD40, CD54, CD80, CD86, MHC class I and II | ++/++ |
| Extracellular matrix proteins | |
| Collagen I, III and IV, vimentin, tenasin | + |
and mitigates the development of tracheal luminal fibrosis. Some other signaling pathways such as CCL2/CCR2 and soluble factors including TNF, IL-10, monocyte chemotactic protein 1 (MCP-1), IL-1, and IL-33 were shown, at least in part, to relate to the migration of fibrocytes in distinct fibrotic diseases [31–33]. Following the recruitment to the tissues, fibrocytes were thought to differentiate into myofibroblasts, driven by TGF-β1, IL-4, and IL-13, and exhibit upregulation of α-smooth muscle actin (α-SMA) and the progressive loss of CD34 and CD45 expression [34].

**Function**

It is complicated to elucidate all the functions of fibrocytes involved in various pathologic processes; however, we might conclude that fibrocytes play different roles to some extent, mainly in inflammation and fibrosis. In other words, there are a number of distinct cytokines produced by fibrocytes that play their corresponding roles during the different stages of disorders. Early studies have shown that fibrocytes express α-SMA and are able to contract collagen gels in vitro, revealing their potential to differentiate into myofibroblasts and contribute to wound contraction [8]. Fibrocytes also produce soluble mediators that induce myofibroblast transformation in culture such as platelet-derived growth factor (PDGF) and TGF-β1 [35], and have been shown to control angiogenesis via secretion of soluble mediators including growth factors (TGF-β, PDGF-A, and fibroblast growth factor (FGF)-7), chemokines (MCP-1 and macrophage inflammatory protein (MIP)-1α), and ECM (collagen I and α-SMA) [36]. As one of the most potent fibrogenic factors, TGF-β1 may facilitate fibroblast transformation both in vivo and in vitro in various fibrotic diseases [25, 37–39]. Wang et al. showed that fibrocytes from humans with chronic airway obstruction could transform to myofibroblasts induced by TGF-β1 in vitro [38]. Neveu et al. considered that TGF-β1 epigenetically regulated the lung fibroblast phenotype in vivo, and inhibition of TGF-β1 DNA methyltransferase could prevent fibrogenesis in the lung and other organs [25]. In the injured liver, a sharp release of TGF-β1 was observed to accompany liver fibrosis, and helped in triggering fibrocyte recruitment to the liver injury site and promoting their differentiation [37, 39]. In fibrotic kidney diseases, several clinical trials and experimental models used pharmacological blockade of TGF-β1 as an antifibrotic therapy to improve or slow the decline in kidney function [40–42]. Moreover, in response to IL-1β, fibrocytes were induced by the secretion of IL-6, IL-8, CCL2, CCL3, and intercellular adhesion molecule-1 (ICAM-1) which would be expected to recruit inflammatory cells [11].

**Fibrocyte involvement in ocular disorders**

Given the conjunction of ongoing inflammation and fibrosis present in many ocular complications, fibrocytes have been proposed to be a critical player in ocular disease. To date, accumulated evidence has demonstrated the involvement of fibrocytes in a wide variety of ocular disorders, including thyroid-associated orbitopathy (TAO), age-related degeneration (AMD), degenerative retinal diseases, intraretinal revascularization, subfoveal choroidal neovascularization (CNV), postoperation scar formation following trabeculectomy, corneal endothelial dystrophy, pterygal fibrous tissues, and vitreomacular traction syndrome and macular hole. A better understanding of cellular mechanisms underlying the regulation of fibrocytes in the initiation and progression of ocular disorders will shed light on the identification of novel therapeutic strategies to treat ocular disease.

**Thyroid-associated orbitopathy**

TAO is an immune-mediated inflammatory disorder usually associated with Grave’s disease (GD) that causes enlargement of the orbital muscles and fat. The molecular mechanisms of TAO are poorly understood. In the past, orbital fibroblasts were thought to be the principal cell type that could give rise to the exophthalmos of patients with TAO, whether or not they were predominantly of the fat or muscle type. Fibrocytes have been shown to be related to inflammation and fibrosis in diverse pathogenesis of tissue remodeling-related disease [22, 43]. Douglas and colleagues found that peripheral blood mononuclear cells (PBMCs) isolated from GD patients yielded approximately fivefold more fibrocytes compared with the control healthy population; however, fibrocyte yields were not statistically different in active TAO patients compared with those with stable disease, and the severity of exophthalmos of the more affected...
orbit failed to correlate with fibrocyte yields [44]. Thyroid-stimulating hormone receptor (TSHR) is an essential antigen of GD expressed at high levels on fibrocytes isolated from patients, consistent with the study by Gillespie et al. [45] that circulating fibrocytes expressed markedly increased TSHR and proinflammatory chemokines in response to TSH. What was more surprising was that the expression of TSHR on fibrocytes was comparable with that found on cultured thyrocytes. In contrast, undifferentiated orbital fibroblasts, even those from patients with GD, failed to express detectable TSHR. These findings revealed that fibrocytes might be involved in the inflammatory response by activating TSHR and producing various chemokines [45]. In healthy humans fibroblasts are uniformly CD34−, and of great potential importance was the finding that those expressing TSHR fibroblasts were uniformly CD34+, strongly suggesting that they derive from circulating fibrocytes [46–48]. In addition, fibrocytes defined as CD34+ and LSP-1+ infiltrated to orbital tissues in large amounts, suggesting that they may migrate to the orbit and mediate tissue reactivity and remodeling through local production of cytokines such as IL-6 and TNF-α [47]. The same group then carried out an in-depth study where they suggested that fibrocytes displayed particularly high levels of functional CD40. CD40/CD40 ligand binding raised the production of several proinflammatory cytokines, amongst which IL-6 expression was mediated through the Akt and NF-κB pathways [49]. The expression and function of CD40 on fibrocytes also suggested that they might provide the antigen-specific T-cell reaction [49]. Douglas’ team also showed that CD40 expression in fibrocytes is induced by TSH and mediates IL-8 expression [50, 51]. Fernando et al. reported that fibrocytes from GD patients not only express TSHR, but also express thyroglobulin (Tg); moreover, GD orbital fibroblasts, which contain CD34+ and CD34− cells, express much lower levels of Tg and TSHR [47]. All these findings indicated that fibrocytes from GD patients are characteristic of multiple thyroid-specific markers by which it potentially shares the derivation with the fibroblast in GD patients. Reducing signaling from TSHR on fibrocytes could be a useful strategy in treating TAO. A theoretical schematic of the roles of fibrocytes in TAO is shown in Fig. 3.

Vitreoretinopathy

Despite many risk factors associated with vitreoretinopathy, inflammation and fibrosis are thought to be the predominant cause in the pathologic process of different ocular fibroproliferative diseases. Proliferative diabetic retinopathy (PDR), one of the proliferative vitreoretinopathies and sequelae of diabetes mellitus, is caused by the inflammation and metabolic changes resulting from diabetes mellitus, which results in vascular leakage with alteration of the phenotype of fibrocytes [52]. Fibrocytes were detected in the vitreous and fibrovascular membrane in PDR patients. Cultured cells from the vitreous of PDR patients exhibited a spindle shape and expressed fibrocyte markers, and these cells could differentiate into myofibroblasts via TGF-β1. These findings indicate that fibrocytes might be involved in the development of PDR [53]. An earlier study revealed that circulating fibrocytes migrated to the

**Fig. 3** A model of fibrocytes in the pathogenesis of thyroid-associated orbitopathy (TAO). Fibroblasts are uniformly CD34− in healthy humans and CD34+ in TAO patients. Fibrocytes appear to infiltrate the orbit in TAO and transition into CD34+ orbital fibroblasts, which express much higher levels of thyroglobulin (Tg) and thyroid-stimulating hormone receptor (TSHR), and mediate orbital inflammation and remodeling. Bovine thyroid-stimulating hormone (bTSH) and M22 are TSHR inhibitors. HLA-DR human leukocyte antigen D-related, IGF-1R insulin-like growth factor-1 receptor, IL interleukin, MCP-1 monocyte chemotactic protein 1, mTOR mammalian target of rapamycin, TCR T-cell receptor, TNF tumor necrosis factor.
epiretinal membranes of proliferative vitreoretinopathy (PVR), differentiated into myofibroblasts, and contributed to wound healing predominantly via the chemotactic CXCL12/CXCR4 pathway [54].

Moreover, an ultrastructural study of patients with vitreomacular traction syndrome revealed that myofibroblasts are the predominant cell type in the epiretinal tissue and the inner limiting membrane of 12 out of 14 specimens [55]. Other ocular fibrotic processes, such as macular hole, also showed that fibrocytes were in the tissue removed at the time of surgery [29]. Taken together, these findings suggested that circulating fibrocytes are a precursor of myofibroblasts in pathologic epiretinal membranes, consistent with the effects of fibrocytes in the process of inflammation and fibrosis of other systemic diseases.

**Corneal wound healing**

The stromal opacity during corneal wound healing is a process associated with precipitation of ECM and myofibroblast generation and persistence. Animal studies revealed that PRM-151, a recombinant form of human pentraxin-2 (also referred to as serum amyloid P), modulated the generation of myofibroblasts after opacity-producing corneal injury in rabbits by inhibiting differentiation of circulating monocytes into fibrocytes and profibrotic macrophages [56]. This finding indicates that PRM-151 inhibited myofibroblast generation after opacity induction, and also suggests that fibrocytes contribute to corneal myofibroblast generation. Furthermore, other investigators have found that bone marrow-derived cells could differentiate into myofibroblasts, with increased expression of α-SMA in the corneal stroma after irregular phototherapeutic keratectomy, and that the presence of these cells within the cornea is associated with corneal stromal haze.

**Pterygium fibrosis**

Pterygium is commonly observed in ocular pathological fibrosis and consists of elastic degeneration of collagen and fibrovascular degeneration [57]. Strong immunoreactivities against progenitor cell markers such as CD34, c-kit, vascular endothelial growth factor (VEGF) receptor 1 and 2 were detected in surgically removed pterygium tissue [58]. CXCR4-positive cells aggregated in the pterygium stroma in response to stromal cell-derived factor (SDF)-1 and might represent the process of differentiation for monocyte precursors into myofibroblasts [59]. A probable cellular mechanism of pterygium formation is that dysregulated healing signaling exceeds the requirement for the recovery of tissue damage, and thereby limbal basal cells will be changed to abnormally altered pterygial cells, and the excessive wound healing process and remnant, altered cells resulted in recurrence using the same mechanism. Clinically, patients with pterygium treated by temporary amniotic membrane patch after pterygium removal were found to have circulating CD34+ cells, which represent the active subset of fibrocytes, increased slightly compared with a marked increase in the bare sclera group; this might represent an effective therapeutic approach for controlling pain—lower collagen expression, and excessive infiltration of bone marrow-derived stem cells [60].

**Other ocular disorders**

Given that they might be a pivotal player in inflammation and fibrosis, circulating fibrocytes have drawn increased attention for the study of ocular disease. Two representative examples of such ocular disorders are postoperational scar formation following trabeculectomy and choroidal neovascularization.

**Conclusions and future directions**

A growing body of literature over the last decade has shown that circulating fibrocytes may serve as an important source of fibroblasts and myofibroblasts during normal or aberrant reparative processes in diverse fibrotic disorders associated with inflammation. Fibrocytes have been implicated in many inflammatory and fibrotic ocular diseases, and their presence at high levels is one of the biomarkers for TAO. Previous studies have demonstrated that both growth factor-induced and hypoxia-driven CXCR4 expression is mediated through the PI3K/mTOR pathway and can be inhibited by rapamycin, which substantially diminished the accumulation of fibrocytes in target tissues. Therefore, the PI3K/AKT/mTOR/CXCR4 signaling pathway may serve as a promising pharmaceutical target to treat ocular disorders. The molecular mechanisms underlying the transformation and differentiation process of fibrocytes into fibroblasts and myofibroblasts remains largely unclear, which also reminds us that fibrosis is not exclusively caused by fibroblasts. How these relative cells correlate with each other phenotypically, how they lose expression of some critical markers (e.g., CD34, CD90), and the inhibition of the pathway should be the concern for the future for a possible therapeutic strategy.

In summary, fibrocytes and the fibrotic process may serve as novel targets for intervention in chronic inflammatory eye diseases. A better understanding of the identity and characteristics of fibrocyte subsets as well as their regulatory mechanisms in ocular disorders will provide valuable insights into the identification of new therapeutic strategies.
