Mortality

Abstract
Background: Concerns have been raised about the escalated mortality in patients of proximal femoral fractures (PPFs) with COVID-19. A meta-analysis to evaluate the mortality in patients with PPFs managed during the current COVID-19 pandemic was conducted.

Methods: A systematic review and meta-analysis of all published studies were conducted with a search on PubMed, Scopus, Web of Science, and Cochrane Library databases using appropriate keywords from January 01, 2020 to January 29, 2021.

Results: 35 relevant studies reporting 4255 patients with hip fracture in the current ongoing pandemic, out of which 692 patients were COVID-19 positive. Twenty studies reported mortality and other relevant statistics on hip fracture patients with and without COVID-19 (4123 hip fracture patients in the year 2020–21, out of which 560 had or were suspected of having COVID-19). A meta-analysis of mortality statistics in patients with and without COVID revealed increased odds of mortality among COVID patients [odds ratio (OR) 6.31, 95% confidence interval (CI) [5.09, 7.83] and meta-analysis on the subgroup of surgically treated patients also showed markedly increased mortality risk among those with COVID-19 (OR 5.99, 95% CI [3.88,9.24].

Conclusion: The mortality risk is markedly increased in hip fracture with concomitant COVID-19 as compared to those without it. This increased risk persisted in those managed surgically. It could be due to the inflammation induced by the fracture or surgery for fracture fixation, further exacerbating inflammation, leading to cytokine storm. It is imperative that such patients are informed regarding increased mortality risk during the consent and shared decision-making process.

1. Introduction
The novel Coronavirus SARS-CoV-2 outbreak started in Wuhan, China, in December 2019, spread globally and has been declared a pandemic by the World Health Organisation on 11th March 2020. Since the novel Coronavirus SARS-CoV-2 outbreak is highly contagious; managing acute trauma and orthopedics had to be rationalized and re-organized to avoid viral transmission and provide a continuity of care. Management of patients with acute orthopedic trauma during the COVID-19 pandemic has been guided by national governments’ recommendations and specialist orthopedic associations. fragile hip fractures in the elderly are obligatory injuries that require prompt surgical management to allow immediate post-operative full weight-bearing mobilization supported by a multi-

disciplinary team to expedite rehabilitation and early supported discharge. The management of proximal femoral fractures (PFF) is still a surgical priority now, with an additional risk factor of COVID-19.\(^4\)

Traditionally the 30-day mortality rate in patients with PFF has been reported to be 5%–8%.\(^1\) However, early limited evidence published so far suggests poor outcomes with high postoperative mortality in patients with a hip fracture and concomitant COVID-19 infection (available studies indicate a mortality rate greater than 30%).\(^5\)–\(^7\) We have undertaken a systematic review and meta-analysis to evaluate the impact of COVID-19 on patients with PFF and assessed associated mortality.

2. **Material and methods**

The protocol for this systematic review has been preregistered on PROSPERO and bears the number CRD42020194409.

Eligibility criteria: We identified studies that met the following criteria.

2.1 **Population**: patients who sustained a proximal femoral fracture (PFF) in the context of COVID-19 or articles focussed on this topic.

2.2 **Intervention**: Replacement arthroplasty for intracapsular fractures. Compression hip screw or intramedullary fixation of the trochanteric or subtrochanteric fractures or nonoperative treatment.

2.3 **Exclusion criteria**: Fracture shaft and distal femur, fracture acetabulum, hip dislocation, revision hip arthroplasty, articles not published in peer-reviewed journals, articles published in other languages were also excluded.

2.4 **Information sources, literature search, study identification, and search**

A systematic search of the PubMed, Scopus, Web of Science, and Cochrane Library databases was performed from January 01, 2020 to January 29, 2021. The keywords used were: ‘COVID-19’ OR ‘Coronavirus’ AND ‘trauma’ OR ‘fracture’ AND ‘hip’ OR ‘proximal femur’ OR ‘neck femur’ OR ‘neck of femur’ OR ‘femoral neck’ OR ‘intertrochanteric’ OR ‘subtrochanteric’). We aimed to identify relevant articles reporting PFF during the COVID-19 pandemic. Reference lists of articles were also screened. A general internet search was undertaken for more relevant papers. We also have hand-searched popular premier Asian orthopedic journals publishing COVID-related papers (e.g., IOJ, JCOT, ABJS) and general medical journals (JAMA, Lancet) to avoid missing any article. Any editorials, opinions, and reviews were considered for qualitative summarization. We excluded articles reporting on non-orthopedic injuries.

Data extraction: Two authors (MKP and VKJ) individually performed the searches, screen the titles and or abstracts, and assessed them. The full text of the potentially eligible studies was independently assessed. Any disagreement was resolved by consultation with the third author (KPI).

Statistical Analysis: We prepared tables to present a narrative synthesis of the findings from the included studies. The descriptive data regarding patient characteristics available from all studies were summarized in tabulated form. Studies reporting data only on COVID-19 patients were analyzed separately. Median (range) was used to summarize the data for continuous variables and frequency/percentage for categorical variables, and appropriate graphics were used for data depiction. Microsoft Excel version 2016 (Windows) was used for analysis.

Meta-analysis on mortality statistics was performed explicitly on studies reporting data on both COVID-19 confirmed/suspect and Non-COVID-19 patients with hip fractures. Study quality of individual studies was accessed using the Newcastle Ottawa scale, wherever applicable. A separate sensitivity analysis was undertaken considering the COVID-19 test positive versus COVID-19 test-negative patients, as reported in the parent studies. Subgroup analysis was also performed for surgically treated patients. We pooled the results using a random-effects meta-analysis (e.g., DerSimonian and Laird method) or fixed-effect meta-analysis as appropriate (A fixed-effects model was employed when I\(^2\)<40% and a random-effects model when I\(^2\) ≥ 40%) and reported odds ratio for mortality in hip fracture patients with and without COVID 19. Heterogeneity between the studies in effect measures was assessed using the Chi\(^2\) and I\(^2\) statistics. Suitable Forest plots and Funnel plots (to depict possible publication bias if we had at least ten studies) were generated. A two-sided P value < 0.05 was taken as statistically significant. RevMan software version 5.3. was used for all meta-analysis.

3. **Results**

3.1 **Literature search**

The systematic search yielded 132 articles on PubMed, 67 on Scopus (All Fields), and 73 on Web of Science. No extra papers were found in the Cochrane library (All Text). Five more papers were discovered on hand search. After screening duplicates and excluding unrelated articles based on the title, 65 papers\(^8\)–\(^72\) with 35 having hip fracture data were finally considered for review after full-text assessment. (Fig. 1, PRISMA flowchart).

Out of these fifteen relevant papers reporting hip fracture, patients with COVID-19 were considered qualitative summarization (Table 1). Twenty papers reported data on both COVID-19 and non-COVID-19 patients with hip fractures and were considered for meta-analysis of 30-day mortality statistics. Rest articles were opinion pieces, general epidemiological studies, Specialist society guideline, infographics analysis, and reviews (7). These 35 studies in total reported a total of 4255 patients with hip fracture in the current ongoing pandemic, out of which 692 patients were positive for COVID-19 (Tables 1 and 2A and 2B).

Fifteen studies, reporting data separately for 158 patients (132 hip fracture patients) with COVID-19 were summarized separately\(^8\)–\(^14,22,24,25,32,33,41,42,44,51,52\) (Table 1). Apart from these, 20 studies reported mortality and other relevant statistics on hip fracture patients with and without COVID-19 (reporting 4123 hip fracture patients in the year 2020–21, out of which 560 had or were suspected to be having COVID-19), but individual patient data was not reported\(^15\)–\(^16,27,28,30,31,44,51\) (Tables 2A and 2B). Study quality of these was accessed using the Newcastle Ottawa scale (Table 3).

Vives et al. reported 136 (123 survived and 13 died) patients, among whom PCR for COVID-19 was done only 23 (16.91%) patients; they did not perform PCR test in the rest of the patients due to low suspicion.\(^73\) They reported detailed data of the seven patients experiencing mortality.

Data from different countries: The majority of papers concerned with hip fractures and COVID-19 came from UK (14) and USA (6). It was followed by articles from Iran (3), Italy (3), China (3), Korea (2), France (2), and Spain (2).

Patient demographics: Among the 132 patients (covered in 15 studies reporting data on only COVID-19 fracture patients), the age range was 28 years–93+ years. There were 56 males and 76 females.

Diagnosis of COVID-19: In the 15 studies, diagnosis of COVID-19...
was established based on positive Computed Tomography scan (CT) or a chest radiograph findings in 32 patients, while 38 patients had a positive Reverse Transcription-Polymerase Chain Reaction (RT-PCR) test report. The RT-PCR availability was limited at several centers in the initial part of the pandemic; therefore, classical chest CT findings were used for COVID-19 diagnosis in most of these patients. However, these tests were positive in all the patients.

Comorbidities: Twenty-one patients were hypertensive, and 51 suffered cardiac disease. Forty had type 2 diabetes mellitus. These comorbidities have been reported as risk factors for mortality in COVID-19 patients in previous studies. Obesity and Chronic Obstructive Pulmonary Disease (COPD) were also considered risk factors for mortality. Some studies also reported patients with prior stroke, Alzheimer’s disease, kidney disease, hypothyroidism, asthma, and cancer (Table 1).

Surgery and nonoperative, conservative care: Out of 132 patients in the 15 studies which report only COVID-19 positive patients with associated PFF, the hip fractures were treated surgically in 116 patients (87.88%). The remaining 16 patients were managed non-operatively (due to comorbidities). All the authors have not explicitly mentioned the exact type of surgery, but in general, it was steered by the fracture morphology, patient comorbidity, and medical fitness. The surgery types varied from an internal fixation with cannulated screws and Dynamic Hip Screw (DHS), or

Infection was confirmed in all by RT-PCR/Chest CT. All had ASA grade 3; 3 cases were operated (one male patient was not operated due to high risk). All four of them expired later (100%) (Letter to Editor).

Authors’ recommendations:
- “Employ multidisciplinary planning with evidence-based approach.
  - Utilize preoperative testing with high level of clinical judgment.
  - Decide on appropriate timing of surgery given risk and severity of COVID-19 and underlying medical condition.
  - Use universal contact and droplet precautions, with aerosol whenever indicated.
  - Choose most optimal surgery and anesthesia technique, with regional anesthesia preferred over general anesthetic.
  - Postoperative course may be further unpredictable with yet unknown morbidity and mortality.”

### 3.2. Mortality risk in hip fractures with and without COVID-19: Meta-analysis

Mortality risk was markedly higher among proven COVID-19 patients/suspected patients with hip fractures than those without it, as depicted in the metaanalysis of 20 studies. (Mantel Haenszel Odds Ratio (MH-OR) 6.31, 95% confidence interval (CI) [5.09, 7.83]; Z = 16.75, p < 0.0001, I² = 26% so Fixed effects model was used) (Fig. 2A and B). Overall, out of 560 covid positive or suspected hip fracture cases, 205 (36.61%) had expired, in contrast to only 306 (8.6%) deaths among non covid cases.

The separate sensitivity analysis considering test positive versus COVID-19 test-negative patients, as reported in the parent studies, also revealed significantly higher among those who test positive for COVID-19 patients with hip fractures than those without it. (MH-OR 5.99, 95% CI [3.88, 9.24]; Z = 11.89, p < 0.001, I² = 18% so Fixed effects model was used). (Fig. 3A and B). 110 (36.1%) of 306 COVID positive hip fracture patients had expired, out of 305 positive hip fracture cases.

Subgroup analysis performed for surgically treated patients revealed significantly higher mortality in hip fracture patients with COVID-19 patients along similar lines (MH-OR 5.99, 95% CI 3.88 to 9.24, Z = 8.08, p < 0.001, I² = 28% so Fixed effects model was used) (Fig. 4). Among surgically treated hip fracture cases 55 (38.73%) experienced mortality out of 142 cases with covid, in contrast to only 55 (7.8%) of 705 cases without covid.

### 4. Discussion

Several studies have evaluated the outcome of hip fracture surgery in COVID-19 patients. It appears equivocal that COVID-19 had an overwhelming effect on managing hip fracture patients during the pandemic, with reportedly increased morbidity and mortality in these patients' cohorts. However, surgical practice in treating principles has remained the same.

Our meta-analysis shows that PFF patients with COVID-19 have higher mortality rates than those without COVID-19. This effect of COVID-19 infection leading to elevated mortality rates persists in the PFF patients treated surgically. A biologically plausible explanation for this effect could be the fracture inflammation or surgery for fracture fixation, further exacerbating inflammation in COVID-19 positive patients, leading to cytokine storm. This must be explained to all patients with PFF and their relatives while undertaking informed consent for surgery. It should form part of the shared decision process. LeBrun et al. have suggested monitoring...
### Table 2B

Summary of studies reporting mortality and other relevant statistics on hip fracture patients with and without COVID-19.

| Author                  | Co-morbidities                  | Orthopaedic Diagnosis and surgery |
|-------------------------|---------------------------------|-----------------------------------|
| Vives JM et al.          | Three had dementia.             | Separate individual patient data for the seven C +ve RT PCR positive fracture patients, who had expired, was provided by Vibes et al, 1 had femoral neck fracture and rest 6 had intertrochanteric fracture. |
| Egol KE et al.           | HTN                             | DM                                |
|                         | DM                              | Dystrophia                       |
|                         | CAD                             | Dementia                          |
|                         |                                |                                    |

| Wignall A et al          | NV                              |                                    |

**Elevated number of deaths within 21 days after surgery.**

In the first two months of the Italian epidemic, in the cities of Piacenza and Parma over 80% of deaths have occurred in patients over 70 years old.
inflammatory markers and delaying surgery until they show a downward trend. However, it is well-known fracture stabilization surgery allows for earlier mobilization and faster rehabilitation.

Male gender and older age are shown to be risk factors for increased mortality in hip fracture patients with COVID-19. However, there is gathering evidence about PFF with COVID-19 infection in younger patients and the unique challenges associated with polytrauma and milder symptoms of COVID-19 in such patients. Elderly patients with hip fractures often present with comorbidities such as diabetes, hypertension, cardiac diseases, COPD, and obesity. Such patients have been noted to face worse with COVID-19 concomitant infection due to their low functional reserves and weaker immunity. A combination of comorbidities and elderly age could make these patients who sustain PFFs more vulnerable to respiratory illness due to their limited pre-injury ambulatory status.

PFF is an obligatory injury that requires prompt surgical management to allow early mobilization, reduce pain, and prevent problems associated with recumbency. According to the prioritization list of surgical procedures, PFF belongs to the group IA requiring surgery to be undertaken 24 h or so from the presentation. Hence appropriate pre-operative medical optimization and an emphasis for surgical stabilization should be undertaken throughout the COVID-19 situation has been a clinical goal. The usual recommendation has been that hip fracture patients should be operated on as soon as they are medically fit. More than 48 h after admission, any surgical delays may escalate the odds of 30-day all-cause mortality.

Early and limited available evidence suggests poor outcomes with high postoperative mortality of more than 20–30% in patients contracting COVID-19 in the perioperative phase. A recent study focused on mortality in surgery (all type) patients with COVID-19; the overall mortality was 23.8% (268/1128). Further analysis revealed 86 deaths from 299 COVID-19 positive orthopedic patients, which comprise 28.8% of the cohort. This included 115 PFF (DHS and Hemiarthroplasty) patients out of a total of 299 surgical interventions but did not show the deaths within these patients.

A recent meta-analysis found that COVID-19 led to deterioration in outcomes in elderly patients with hip fractures and was associated with higher short term mortality. Authors recommended a multidisciplinary approach to manage such “pandemic within a pandemic”.

Doglietto et al. described mortality in 57 PFF patients, out of which 19 were COVID-19 positive. Twelve patients underwent femoral nail fixation, and hip hemiarthroplasty was performed in seven patients. It was not clear from the study how many patients had a proximal femur fracture and deaths or complications. Intertrochanteric fractures were more commonly seen than the femoral neck and subtrochanteric fractures. The incidence of mortality was slightly higher in intertrochanteric fractures.

Though there has been an earlier pandemic phase, subsequent studies still recur significantly higher 30-day mortality rates than the traditionally quoted figures of 5%–8%.

Egol et al. stated that surgery for COVID-19 positive hip fracture patients was delayed by about one day (to allow for optimization) than non-COVID-19 patients. They have expressed concern whether this delay might have contributed to increased mortality. Konda et al. found that the STTGMA tool can be utilized for the COVID-19 virus, thus providing a robust risk evaluation technique. COVID-19 positive/suspected status in hip fracture patients indicates a high risk for perioperative morbidity and mortality. These authors suggest that surgery should be deferred for hip fractures in these patients until symptoms improve or resolve. Patients should be reassessed for surgical treatment versus conservative care.

Segarra et al. reported surgery in two hip fractures; none of them received intensive care unit support. One patient expired, and the other recovered after 48 h of supportive care and was discharged.

Mi et al. studied 145 hip fractures (delayed surgery 108, nonoperative 37) and concluded that delayed surgery is more beneficial and has fewer complications than conservative treatment. Furthermore, delayed surgery led to decreased pain which increased mobilization and better function.

Recently, data on a large multicentre study (IMPACT Scort 2) found that the COVID-19 was independently associated with three times higher 30-day mortality risk in hip fracture patients. And, nearly half were acquired during hospital stay (i.e., nosocomial COVID 19). Diagnosis of COVID-19 within six days was associated with male sex and COVID-19 symptoms. In contrast, Diagnosis of COVID-19 between 7 and 30 days of hospital admission was associated independently with male sex, Nottingham Hip Score ≥7, lung disease, ASA grade ≥3, and length of stay ≥ nine days.

The orthopedic community's challenge is finding a balance of providing an effective treatment option for PFF and achieving the best eventual outcome for these patients to reduce mortality and be mindful of associated risk factors and comorbidities.

### 4.1. Limitations of the study

These studies were done in different geographical populations. Consequently, availability, quality of medical care, and surgical facilities may vary. These factors may reflect on clinical outcomes. Only a few studies focussed on the PFF exclusively, whereas others had included all types of fractures. All relevant variables were not reported uniformly in the studies. There is a lack of uniformity in the patient population, which may affect the risk of mortality and morbidity. Follow up period of patients was also variable, and relatively short-term outcomes have been reported. Extended outcomes have not been described. In-patient and 30-day mortality was explicitly mentioned in a few studies only.

Another limitation of the study has been the nature of studies that have been reported and available for analysis. Any study based on the recruitment of retrospective cohort studies is prone to various bias and confounding factors, particularly of publication and detection bias. However, we have utilized funnel plots to explore the potential of publication bias. To mitigate detection bias, evaluation of relevant recent literature and application of PRISMA reporting principles of a systematic review have been incorporated.

### 5. Conclusion

This systematic review and meta-analysis confirm that hip fracture patients with COVID-19 have significantly higher mortality rates than non-COVID patients. The 30-day mortality rates are also higher in these groups of patients. The enhanced effect of COVID-19 infection leading to elevated mortality rates persists in hip fracture patients treated surgically. The likely contributory factors for increased mortality are inflammation caused by the fracture and the surgery (leading to Cytokine-storm), advanced age, male sex, and perhaps early surgical intervention. Informed consent must include a disclosure of the increased risk of mortality after the surgery of PFF and must be explained clearly to the patient and their relatives. The treating surgical team should carefully do a full risk-benefit analysis. A comprehensive best practice guideline to mitigate the risk posed by COVID-19 will help healthcare professionals worldwide improve clinical outcomes.

Fig. 2A. Forrest and Funnel plots of comparison of hip fractures mortality rates among COVID-19 patients suspects vs. non-COVID-19 patients.
**Fig. 2B.** Forrest and Funnel plots of comparison of hip fractures mortality rates among COVID-19 patients suspects vs. non-COVID-19 patients.

**Fig. 3A.** Forrest and Funnel plots of comparison of hip fractures mortality rates among COVID-19 positive vs. non- COVID-19 positive patients.

**Fig. 3B.** Forrest and Funnel plots of comparison of hip fractures mortality rates among COVID-19 positive vs. non- COVID-19 positive patients.
Funding statement

All our clinical procedures were fully compliant with the ethical standards following the local consenting and ethics guidelines. The current submitted article is not a clinical study and does not involve any patients.

Author’s contributions

VK and GKU involved in Conceptualization, literature search, manuscript writing, and editing. MKP and KPI Literature search, authors read and agreed the final draft was submitted.

Funding statement

The authors have not declared a specific grant for this research from any funding agency in public, commercial or not-for-profit sectors.

Disclosure statement

Nothing to disclose. “The authors declare no conflict of interest.”

Declaration of competing interest

Authors have no competing interests to declare.
