(March 31, 2022)

The nucleus $^{54}$Mn has been observed in cosmic rays. In astrophysical environments it is fully stripped of its atomic electrons and its decay is dominated by the $\beta^-$ branch to the $^{54}$Fe ground state. Application of $^{54}$Mn based chronometer to study the confinement of the iron group cosmic rays requires knowledge of the corresponding halflife, but its measurement is impossible at the present time. However, the branching ratio for the related $\beta^+$ decay of $^{54}$Mn was determined recently. We use the shell model with only a minimal truncation and calculate both $\beta^-$ and $\beta^+$ decay rates of $^{54}$Mn. Good agreement for the $\beta^+$ branch suggests that the calculated partial halflife of the $\beta^-$ decay, $(4.94 \pm 0.06) \times 10^7$ years, should be reliable. However, this halflife is noticeably shorter than the range $1-2 \times 10^8$ y indicated by the fit based on the $^{54}$Mn abundance in cosmic rays. We also evaluate other known unique second forbidden $\beta$ decays from the nuclear p and sd shells ($^{10}$Be, $^{22}$Na, and two decay branches of $^{26}$Al) and show that the shell model can describe them with reasonable accuracy as well.

I. INTRODUCTION

The nucleus $^{54}$Mn decays in the laboratory dominantly by electron capture to the $2^+$ state in $^{54}$Cr with the halflife of 312 days. However, as a component of cosmic rays, $^{54}$Mn will be fully stripped of its atomic electrons, and this mode of decay is therefore impossible. The $^{54}$Mn nuclei were in fact detected in cosmic rays using the Ulysses spacecraft [12]. They offer an attractive possibility to use their measured abundance as a chronometer for the iron group nuclei (Sc - Ni) in cosmic rays in analogy to the chronometers based on the abundances of other long lived isotopes ($^{10}$Be, $^{26}$Al, and $^{36}$Cl). With them one can, in turn, determine the mean density of interstellar matter, a quantity of considerable interest. The use of the long lived nuclei as cosmic ray chronometers is reviewed in Ref. [3]. The importance of $^{54}$Mn for the understanding of propagation of the iron group nuclei that are products of explosive nuclear burning have been stressed in Refs. [15,16]. For this program to succeed, however, one must know the halflife of the stripped $^{54}$Mn ($I^\pi = 3^-$). The decay scheme of $^{54}$Mn is shown in Fig. 1; the dashed lines indicate the decay paths of the stripped $^{54}$Mn.

In two recent difficult and elegant experiments the very small branching ratio for the $\beta^+$ decay to the ground state of $^{54}$Cr has been measured: $(2.2 \pm 0.9) \times 10^{-9}$ [17] and $(1.20 \pm 0.26) \times 10^{-9}$ [18]. By taking the weighed mean of these values we extract the averaged branching ratio of $(1.28 \pm 0.25) \times 10^{-9}$. Combining it with the known halflife for $^{54}$Mn of 312.3(4) d [5], it corresponds to an experimental partial $\beta^+$ halflife of $(6.7 \pm 1.3) \times 10^8$ years. As explained in [19,20] one expects, however, that the decay of the fully stripped $^{54}$Mn will be dominated by the at present unobservable $\beta^-$ decay to the $^{54}$Fe ground state. Previously, the partial $\beta^-$ halflife was estimated assuming that the $\beta^-$ and $\beta^+$ form factors are identical. Very recently, in Ref. [21], the ratio of the $\beta^-$ and $\beta^+$ form factors was calculated using a very truncated shell-model and extending it by comparison with similar calculations in the sd-shell. The estimated $\beta^-$ halflife is $(6.3 \pm 1.3) \times 10^9$ y [22]. In this work we will use the state of the art shell model and evaluate not only the EC decay rate of the normal $^{54}$Mn, but also both decay branches of the unique second forbidden transitions $^{54}$Mn($3^+$) $\rightarrow$ $^{54}$Cr($0^+$) and $^{54}$Mn($3^+$) $\rightarrow$ $^{54}$Fe($0^+$). By comparing the calculated $\beta^-$ decay halflife (or branching ratio) to the measured one we hope to judge the reliability of the calculation. We then proceed to calculate the halflife of the unknown $\beta^-$ decay.

The decays of stripped $^{54}$Mn are unique second forbidden transitions which depend on a single nuclear form factor (matrix element). Halflives of several such decays in the p shell ($^{10}$Be) and sd shell ($^{22}$Na, and two decay branches of $^{26}$Al) are known and have been compared to the nuclear shell model predictions in Ref. [23]. For the sd shell nuclei, however, only calculations in a severely truncated space were performed in [23]. Since that time computation techniques and programming skills have improved considerably. Thus, in order to further test our ability to describe this kind of weak decays, we repeat the analysis [21], using the exact shell model calculations without truncation. At the same time the availability of new (and different) experimental data for the $^{10}$Be [24] and $^{26}$Al [25] decays make necessary a new comparison between experiment and calculations.

In order to evaluate the decay rate we use the formulation of [12]. The number of particles with momentum...
\( p \) emitted per unit time is:

\[
N(p_c) dp_c = \frac{g^2}{2\pi^3} p_c^2 F(Z, W_c) C(W_c) dp_c,
\]

(1)

where \( g \) is the weak coupling constant, \( p_c \) and \( W_c \) are electron (or positron) momentum and energy, \( \nu \) is the neutrino (or antineutrino) momentum, and \( Z \) is the atomic number of the daughter nucleus. All momenta and energies are in units where the electron mass is unity. For the Fermi function \( F(Z, W_c) \) we use the tabulated values, and the shape factor \( C(W_c) \) for the case of the unique second forbidden transitions is of the form

\[
C(W_c) = \frac{R^4}{15\pi} \left| A F_{32}^{(0)} \right|^2 \left[ p + \frac{10}{3} \lambda_2 p_2^2 + \lambda_3 p_3 \right].
\]

(2)

The nuclear form factor, in turn, is defined as

\[
A F_{32}^{(0)} = 9\lambda \sqrt{\frac{4\gamma}{2J+1}} \left( \frac{f|\tilde{r}^2[Y_2 \times \sigma]|^3 t_{2|} |i|} {R^2} \right)
\]

(3)

where \( i \) denotes the initial state and \( f \) the final one; the matrix element is reduced with respect to the spin space only (Racah convention \([9]\)); \( \pm \) refers to \( \beta^\pm \) decay; \( t_{2|} = (\tau_x \pm i \tau_y)/2 \), with \( t_{+\mu} = n \); \( g_A = -1.2599 \pm 0.0025 \) \([14]\); and \( R \) is the nuclear radius (the final expression for \( C(W_c) \) is obviously independent of \( R \)).

The functions \( \lambda_2 \) and \( \lambda_3 \) are tabulated in \([12]\). Integrating the rate formula up to the spectrum endpoint we obtain the expression for \( 1/\tau \) and, respectively, for the half-life \((T_1/2 = \ln(2)/\tau)\) in terms of the nuclear form factor squared. (For the stripped atoms we correct the endpoint energy accordingly.) For the quantity \( 2\pi^3 \ln(2)/g^2 \) we use the value 6146 ± 6 s \([14]\). Note the usual \( \lambda \) value, commonly used to characterize a decay, uses the integrated phase space factor \( f \) of Eq. (1), however without the constant \( g^2/(2\pi^3 15^2) \) and the radius factor \( R^4 \).

### II. SHELL MODEL CALCULATIONS

In our calculation we consider an inert core of \(^{40}\)Ca with the 14 remaining nucleons distributed throughout the \( pf \)-shell. We use KB3 \([8]\) as the residual interaction with the single particle energies taken from the \(^{41}\)Ca experimental spectrum. The Hamiltonian is diagonalized with the code ANTOINE \([14]\) using the Lanczos method. It is not yet possible to perform a full \( pf \)-shell calculation but we can come fairly close. Let’s denote by \( f \) the \( f_{7/2} \) orbit and by \( r \) the rest of the \( pf \) shell \((p_{3/2}, p_{1/2} \) and \( f_{5/2} \)). From the calculations of reference \([14]\) we know that one can get a good approximation to the results in the full \( pf \)-shell calculation when one considers the evolution of a given quantity as the number of particles, \( n \), allowed to occupy the \( r \)-orbits, increases. We have extended the calculations of the previous reference allowing up to a maximum of \( n = 7 \) particles in the \( r \)-orbits. The \( m \)-scheme dimensions for this calculation are: 17,136,878 for \(^{54}\)Cr; 49,302,582 for \(^{54}\)Mn; 91,848,462 for \(^{54}\)Fe. Figure 2 shows the variation of the nuclear form-factor for the \( \beta^+ \) and \( \beta^- \) transitions as a function of the truncation level \( n \). We have used the harmonic oscillator wave functions with \( b = 1.99 \) fm. From Figure 2 it is clear that our calculation has already converged for the \( n = 5 \) truncation. It is also obvious that it would be inappropriate to use only the lowest order corrections \((n = 2 \) for \( \beta^- \) and \( n = 3 \) for \( \beta^+ \)).

To see how well the calculated wave function reproduces basic characteristics of the ground state of the odd-odd nucleus \(^{54}\)Mn, note that the electric quadrupole moment is calculated to be \( Q = 34 \) e fm\(^2\) (with effective charges \( e_\pi = 1.5 \) and \( e_\nu = 0.5 \)), while the experimental value is \( Q = 33 \pm 3 \) e fm\(^2\). The magnetic moment, calculated with the free nucleon gyromagnetic factors is \( \mu = 2.78 \mu_N \), while the experimental value is \( \mu = 3.2819 \pm 0.0013 \mu_N \). We have also calculated the \( \log f \) value for the Gamow-Teller electron capture transition to the \( 2^+ \) state in \(^{54}\)Cr. The calculated \( \log f \) is 6.14, where we have used the usual quenching factor of 0.76, is in good agreement with experimental value of 6.2. Note, however, that quenching of this allowed Gamow-Teller matrix element is needed to achieve the agreement with the experimental rate. (See \([18]\) and references therein for the problem of the GT strength quenching.)

From Eq. (8) we know that the single particle matrix elements needed for the evaluation of the form factor involve the expectation value of \( r^2 \) between the single-particle radial wave functions. In the evaluation of this quantity we have followed two approximations. First, we consider harmonic oscillator wave functions. In this case all matrix elements are proportional to the square of the length parameter \( b \). We use the prescription of reference \([19]\) to determine \( b \) from the experimental charge radius \((r_{ch}^{2/3}) \) of the parent nucleus; this leads to \( b = 1.99 \) fm in \(^{54}\)Mn. Second, we consider Woods-Saxon radial wave functions. They have been obtained using the potential well that includes spin-orbit and Coulomb terms \([21]\). The radial parameter of the well has been adjusted to reproduce the experimental charge radius. The values of the form factor and half-lives obtained using both methods are listed in Table 1.

We have also evaluated the other known unique second-forbidden beta decays: \(^{10}\)Be(\(\beta^-\))\(^{10}\)B, \(^{22}\)Na(\(\beta^+\))\(^{22}\)Ne and \(^{26}\)Al(\(\beta^+\))\(^{26}\)Mg. For the \( sd \)-shell nuclei we consider an inert core of \(^{16}\)O and the \( sd \)-shell as the valence space. These transitions were previously computed in Ref. \([11]\) using a truncated shell-model calculation. In our case, without truncating the \( sd \) shell space, we use the Wildenthal USD effective interaction \([22]\) and determine the radial parameters following the procedure outlined in the previous paragraph. In the harmonic oscillator approximation we use \( b = 1.78 \) fm for \(^{22}\)Na and \( b = 1.81 \) fm for \(^{26}\)Al. Table 1 contains the results of our calculations. For the decay of \(^{10}\)Be we reproduce the results of reference \([11]\), however our determined \( b \) parameter, 1.75 fm,
is slightly larger than the one used before \((b = 1.68 \text{ fm})\).
The new experimental value for the half-life \([10]\) nicely agrees with the computed one.

### III. RESULTS AND DISCUSSION

The top row of Table [14] shows that our shell model result agrees with the measured half-life of the \(\beta^+\) decay \(^{54}\text{Mn} \rightarrow ^{54}\text{Cr}\) within errors, without quenching of the corresponding form factor. The calculated \(\beta^-\) half-life, \((4.94 \pm 0.06) \times 10^5 \text{ y}\) (if we arbitrarily take the average value between HO and Wood-Saxon calculations), is noticeably shorter than the range expected in Refs. \([11,12]\) \((1.2 \times 10^6 \text{ y})\) based on the experimental abundance of \(^{54}\text{Mn}\) in cosmic rays and the model of the cosmic ray confinement.

Our calculation suggests that the form factor for the \(\beta^-\) decay, \(11.7 \text{ fm}^2\), is larger than the form factor for the \(\beta^+\) decay, \(7.8 \text{ fm}^2\). We can offer some intuitive, albeit very crude, understanding of this difference. Let us treat the three nuclei in the extreme single particle model. Also, instead of the actual transitions connecting the odd-odd nucleus \(^{54}\text{Mn}\) with the corresponding even-even ground state, let us consider the transitions from the seniority zero even-even nuclei to the odd-odd one. The \(\text{Cr} \rightarrow \text{Mn}\) transition would then involve \((\pi f_{7/2})^3(\nu p_{3/2})^2 \rightarrow (\pi f_{7/2})^5(\nu p_{3/2})^2\), changing a \(p_{3/2}\) neutron into a \(f_{7/2}\) proton. In contrast, the \(\text{Fe} \rightarrow \text{Mn}\) would involve \((\pi f_{7/2})^3(\nu p_{3/2})^5(\nu p_{3/2})^2\), changing a \(f_{7/2}\) proton into a \(p_{3/2}\) neutron. Using the above naive assignments, we are led to the conclusion that the \(\beta^-\) form factor should be about \(\sqrt{3}\) times larger than the \(\beta^+\) form factor. Even though the detailed shell model results are not fully determined by the indicated single particle transitions (but they are the largest ones), the overall scaling factor emerges.

Among the \(sd\) shell transitions in Table [14], the transition to the \(1.8 \text{ MeV}\) state in \(^{26}\text{Mg}\) agrees perfectly with the experiment, while the calculated form factors for the other two are somewhat larger, by a factor of about 1.5, than the experimental value. For \(^{40}\text{Be}\) decay the calculated form factor is also a bit larger. We cannot, therefore, draw any conclusion about the necessity of quenching in the case of the unique second forbidden transitions. While the lighter \(p\) and \(sd\) shell nuclei contain perhaps a hint that quenching is needed, it would obviously spoil the agreement in the case of the \(\beta^+\) branch of the \(^{54}\text{Mn}\) decay.

In conclusion: Our shell model calculations reproduce the experimental half-lives of the unique second forbidden beta decays within a factor of less than two. No clear evidence for the quenching of the corresponding form factors emerges. For the stripped \(^{54}\text{Mn}\) decays, the shell model describes the \(\beta^+\) branch within errors. It predicts that the form factor for the \(\beta^-\) decay is larger than the one for the \(\beta^+\) decay. The calculated \(\beta^-\) half-life (and there-fore also the total halflife) is noticeably shorter than the range based on the observation of \(^{54}\text{Mn}\) in cosmic rays. This conflict, albeit relatively mild, makes attempts to determine the branching ratio for the \(\beta^-\) decay experimentally even more compelling.
