Introduction

Radical surgery in advanced cancers of the pelvis poses great technical difficulties not only in the resection of the tumor but also in the reconstructive process. This type of "salvage surgery" can compromise the quality of life of the patients. This article describes two procedures that reduce reconstructive surgical complications and improve the patient's quality of life.

Laparoscopic Vaginal Diverticulization (LVD)

This technique uses the property of the mucous membrane in which when subjected to constant pressure tends to form a diverticulum. The mucous layer has a good blood supply and can resist pressure without suffering necrosis. It responds adapting to the pressure and grows forming a diverticulum. This can be seen in diverticular colon disease. The colon diverticulum consists only of mucous and serous layers. To remove the vagina completely a perineal approach is performed for the distal sectioning of the vagina which is removed in continuity with the uterus. The mucous tissue is closed at the level of the introitus. 6 to 8 weeks after surgery we perform this procedure to form a neovagina. We use a resin marble of 3 centimeters in diameter with two convergent drillings as shown in (Figure 1).

Then a silkthread number 1 is placed. This is to extract the marble to form the diverticulum of the vaginal mucous tissue (Figure 2). The procedure is completely laparoscopic. The camera is placed through the umbilicus and two mini graspers are introduced on both sides [1]. Under laparoscopic view the silk thread that holds the marble is inserted through the vaginal remnant with a needle. The silk thread is entered into the abdominal cavity. Care must be taken not to injure the...
bladder or the rectum. Once the silk thread endings are within the abdominal cavity the needle is removed.

The two mini graspers that have been introduced laterally are reinserted into the preperitoneal space to the point where the silk threads of the marble were introduced. Pulling the end of each silk thread with the mini grasper the threads are extracted through the preperitoneal space until they are exteriorized through the lateral incisions. The ends of the silk threads are attached to a plastic structure that permits to increase the tension gradually. The tension of the silk threads is increased every day generating the formation of the extra peritoneal vaginal diverticulum (Figure 3). Thus a neovagina is generated without using other tissue of the patient. The result is very aesthetic and functional. A vaginal dilator is used to finish the process of vaginal diverticulization.

Reconstruction of pelvic diaphragm (RPD)

This surgical technique reduces the risk of perineal evisceration after pelvic exenteration in which most of the pelvic diaphragm has been removed. It is also used when there is a large defect in the pelvic diaphragm that may cause a pelvic floor hernia. We have used this procedure in cases of advanced prostate, bladder, rectum or uterine cancers. Normally we perform pelvic exenteration in highly selected patients who have a persistent tumor after radical radiotherapy and chemotherapy. The tumor should have less than 10 cm diameter and should not be fixed to the pelvic walls. Patients are explained of the consequences of this procedure and undergo psychological evaluation to determine if they are suitable candidates for this type of surgery.

After performing the pelvic exenteration a segment of sigmoid colon is mobilized preserving its irrigation with the marginal vessels and the upper hemorrhoidal vessels [2-4]. The mobilized sigmoid segment is opened longitudinally along its antimesenteric border. Then using hydro dissection the entire mucosa is removed. The denuded mucosa surface is placed down and fixed to the pelvic walls so that a new pelvic diaphragm is formed containing muscular and serosal layers. The muscular layer supports the visceral contents of the pelvic cavity (Figure 4). This reduces the risk of perineal dehiscence.

Conclusion

Radical surgical procedures such as Pyver IV hysterectomy, vaginectomy and pelvic exenteration are considered “salvage surgery” because aesthetics and functionality become secondary priorities. With these procedures the only goal is to save the patient’s life. But the development of new reconstructive techniques as the ones described above will help to improve the quality of life of our patients.
