Analysis of the carbon-rich very metal-poor
dwarf G77-61 *

Received; accepted

Abstract. We present an analysis of the carbon dwarf G77-61, a known binary, based on high resolution Keck spectra. G77-61 has a very-low metallicity, although not as extreme as what was previously conjectured. This star is very carbon-enhanced, the spectra showing very strong CH, CN, and C2 bands of both 13C and 12C isotopes. Atomic lines are sparse, and often blended, but we were able to derive abundances for Na, Mg, Ca, Cr, Mn, and Fe. Its [Fe/H] of -4.03±0.1 places it among the lowest metallicity stars known, and its very high [C/Fe]=+2.6, and [N/Fe]=+2.6 among the most C and N-rich metal-poor stars. The carbon isotopic ratio is 12C/13C=5±1. No overabundance of s- or r-process elements is detectable, but the upper limits that can be set on these overabundances are not very constraining.

Key words. Stars: abundances ; Stars: carbon ; Stars: Population II ; Stars: individual: G77-61

1. Introduction

The star G77-61 was first identified as a nearby carbon dwarf by Dahn et al. (1977). They re-analyzed its previous parallax determination by Routly (1972) to find $M_V = +9.6 \pm 0.6$ mag. Dearborn et al (1986) established that G77-61 is a binary with an unseen companion and with a period of ~245 days, suggesting a cool white dwarf of much higher mass than the visible object as the second star. The primary was later spectroscopically analysed by Gass et al. (1988), who
concluded that its metallicity was extremely low, [Fe/H] = −5.5 dex (on our adopted scale with logA(Fe) = 7.45). No other spectroscopic investigation has been carried out since then.

The discovery of a large number of very metal-poor, carbon-rich objects, with diverse additional peculiarities, particularly \( r \)-process or/and \( s \)-process enrichment, and the discovery of the most iron-poor star known, HE0107−5240 (Christlieb et al. 2002), at [Fe/H] = −5.3, which is also very C-rich, all contribute to a renewed interest in the star G77-61.

2. Observations

The star G77-61 was observed several times using HIRES (Vogt et al., 1994) at the Keck Observatory. The first set of spectra (3 exposures, each 1200 sec long) were obtained on the night of Sep 29, 2002. They covered a spectral range from 3780 to 5320 Å, at a resolution of 34 000 with small gaps between the orders at the red end of the range. A 1.1 arcsec wide slit was used, and a signal to noise ratio (SNR) of 100/spectral resolution element (4 pixels wide) in the continuum in the middle of this spectral range was achieved. This was calculated assuming Poisson statistics and ignoring issues of cosmic ray removal, flattening etc. The star was re-observed August 19, 2003 to cover the region from 5000 to 7900 Å, with a resolution of 34 000. Three separate exposures were required for full spectral coverage. On line signal calculations used the order just blueward of the center of the CCD at a wavelength of 5865 Å. Much shorter exposure times were required to achieve the desired SNR of 75 to 100/spectral resolution element as the star is so red.

These spectra were reduced using a combination of Figaro scripts (Shortridge 1993) and the software package MAKEE\(^1\). Normal procedures were followed until the final step, which involves fitting a low order polynomial to the continuum to remove the last residuals of the variation of the instrumental response with wavelength. Since the continuum is essentially impossible to determine in this heavily banded star, even at this spectral resolution, this step was omitted. Typical residuals removed at this stage are about 10% of the mean continuum within an order and are locally smooth.

The observed heliocentric radial velocity for G77-61 is −29 km/s on September 29, 2002, and −20 km/s on August 19, 2003, with somewhat large uncertainty due to the strong veiling. These values fit very well with those predicted from the orbit of Dearborn et al. (1986): −29.6 and −18.5 km/s.

3. Analysis

The spectra were analysed through spectrum synthesis, the very strong veiling by molecular bands not allowing equivalent width determinations.

---

\(^1\) MAKEE was developed by T.A. Barlow specifically for reduction of Keck HIRES data. It is freely available on the world wide web at the Keck Observatory home page. [http://www2.keck.hawaii.edu:3636/](http://www2.keck.hawaii.edu:3636/)
3.1. stellar parameters

Our B-V photometry from the Swope 1-m telescope at the Las Campanas Observatory, (Ivans & Cohen, private communication), $B=15.70$ and $V=13.97$, gives $B-V=1.73$ mag. Dahn et al. (1977) provide $V=13.90$, $B-V=1.70$. The trigonometric parallax of 16.9±2.2mas (Harris et al. 1998), and the V magnitude lead to $M_V=10.1\pm0.27$, assuming no reddening, as the star is nearby. Schlegel et al.'s extinction maps (1998) give $E(B-V)=0.100$ at this position. The Galactic latitude of G77–61 is $-41.51^\circ$, corresponding to a height of 39 pc above the Galactic plane, resulting in about 25% of the total extinction, or 0.025 mag, well below all other uncertainties. The IR colours $J-H=0.684$, $H-K=0.337$, and $J-K=1.007$ in the Johnson system (Bessell & Brett 1988) are obtained from 2MASS photometry (Skrutskie et al. 1997, and Cutri et al. 2003) $J=11.470\ (0.022)$, $H=10.844\ (0.024)$, $K=10.480\ (0.019)$, using the relations of Carpenter (2001). The K magnitude is 10.52 in the Johnson system, which transforms to an absolute $M_K=6.62\pm0.27$. Carbon-rich dwarf MARCS models around $T_{\text{eff}}=4000$ K and $[\text{Fe/H}]=-3$ or $-4$ have bolometric corrections $BC_K\approx2.25$, and $BC_V\approx-0.65$. Thus, the absolute bolometric magnitude is $M_{\text{bol}}\approx9.45$ from $V$, and 8.87 from K. Dearborn et al. (1986) find $BC_V=-0.96$ from spectro-photometric observations, leading to $M_{\text{bol}}=9.14$. We adopt the average of the K and V values, $M_{\text{bol}}=9.16$ (i.e. $L=0.017L_\odot$).

We adopt $T_{\text{eff}}=4000\pm200$ K, obtained from interpolating the observed V-J and V-K colors in the predicted color grid of Houdashelt, Bell, & Sweigart (2000). We assume that the star is sufficiently nearby that the reddening is negligible. The uncertainty in $T_{\text{eff}}$ is not due to the observational photometric errors but rather to the modeling uncertainties. The Houdashelt, Bell, & Sweigart (2000) color grid was calculated assuming scaled Solar compositions extending to $[\text{Fe/H}]$ as low as $-3$ dex, but G77–61 has a highly anomalous composition with very large C excess. The C$_2$ bands reduce the flux integrated over the V bandpass below that of the true continuum by $\sim35\%$. The effect of the prominent C$_2$ absorption, which is not included in the models at all, has been compensated for in an approximate way, but still leaves a large uncertainty in $T_{\text{eff}}$. The range of $T_{\text{eff}}$ from the three previous analyses of this star listed in §1 is 4000 to 4200 K.

For $T_{\text{eff}}=4000$ K we deduce that $R=0.27\ R_\odot$, and $\log\ g=5.27$ assuming $M=0.5M_\odot$; assuming $M=0.3M_\odot$ leads to $\log\ g=5.05$.

While evolutionary tracks for metal poor stars with such extreme C enhancement are not available, the new Yale-Yonsei isochrones (Kim et al. 2002, Yi et al. 2003) with $\alpha$-enhancement give an indication of whether these values are in accord with those expected for an old lower main sequence star. We examine the sequence of metal poor isochrones with $\alpha$-enhancements of a factor of four and age of 9Gyr. The inferred luminosity of G77-61 then corresponds to a mass of $0.38M_\odot$. The $T_{\text{eff}}$ of the isochrone at this luminosity, which is probably quite uncertain, is $\sim300$ K lower than the value we adopt.
3.2. model atmospheres and line data

Using the estimates of $T_{\text{eff}}$ and log $g$, models were calculated with the MARCS code (Gustafsson et al. 1975, Plez et al. 1992, Edvardsson et al. 1993, Asplund et al. 1997, Gustafsson et al. 2003), at metallicities between $-5$ and $-3$, for various C/H ratios. The synthetic spectra were computed with the TURBOSPECTRUM package (Alvarez and Plez 1998), using atomic lines from the VALD database (Kupka et al. 1999). The data for the lines we use in the abundance analysis is listed by Hill et al. (2002), and Cayrel et al. (2004). The molecular line lists for CH, and CN were specially assembled. These lists, used by Hill et al. (2002), were further updated. The CH line list was improved by shifting a number of line positions by 0.1 Å or less between 4200 and 4275 Å, for $^{13}$CH A-X lines, and to a lesser extent $^{12}$CH lines (using in particular Richter & Tonner, 1967, as well as a Keck spectrum of the carbon-rich metal-poor star HE0212-0557). The C$_2$ line list was taken from Querci et al. (1971), and updated by scaling the gf-values to agree with modern lifetime and intensity measurements (Cooper and Nicholls 1975, Grevesse et al. 1991, Erman and Iwamae 1995, Langhoff et al. 1990). The situation is far from satisfactory for spectrum synthesis with this latter list, and efforts are under way to improve the situation. We did not use C$_2$ lines to derive the C abundance, and avoided the use of other lines situated within C$_2$ bands, where a risk of blending exists.

It is important to use a model computed with abundances close to the spectroscopic determination. Figure 1 shows the thermal and pressure structure of the final model adopted, with abundances from Table 1 together with a second model with solar abundances uniformly scaled down by $-4$ dex and with [α/Fe]$=+0.4$, and a third model with in addition CNO abundances set to their final values. The thermal structure of the model is affected by the abundance of species that contribute importantly to the opacity (mostly C and N, due to the predominance of C$_2$ and CN in the spectrum), and less importantly by the abundance of electron donors (Mg, Na, and Ca) which has a impact on the T-P-$P_{\text{gas}}$ relation in the outermost layers. This is further illustrated in the spectrum synthesis. Changing from a model with scaled solar abundances ([X/H]$=-4.0$), and [α/Fe]$=+0.4$, to a model with the abundances of Table 1 results for example in a change of more than 0.3 dex in the determination of the abundance of Na from the Na I D line. This is illustrated in Figure 2 where synthetic spectra computed with various Na abundances in the three model atmospheres are compared to the observation. In the case of the two models with equal abundances of C, N, and only differences in some elements (esp. Na, Mg, Ca), the differences are due to the impact of the electron donors in the line forming layers. They resulting difference is about 0.1 dex in the determination of the Na abundance. Interestingly, deeper in the atmosphere, around $\tau_{\text{Ross}}=1$, about 80% of the electrons arise from H$_3^+$. The obvious impact this has on H$^-$ opacity demonstrates the importance of including H$_3^+$ in the molecular equilibrium, as recently shown for the evolution of zero-metal stars by Harris et al. (2004). We use the partition function of Neale & Tennyson (1995) for H$_3^+$. 
Fig. 1. Effect of abundance changes on model atmosphere thermal and pressure structure. Full line is the final model, with the abundances of Table 1; dashed line is a model with solar abundances scaled by $-4$ dex, and $[\alpha/Fe]=0.4$, dotted line has in addition CNO abundances to their final value.

The effect of changes in C and N abundances on the emergent spectrum is even more dramatic, through the change in blanketing of $^{12}$C$_2$, CN and CH, which affects the thermal structure of the model (see Figure 1 and 2). The O abundance, which we cannot determine, has no impact as long as it stays well below the C abundance. Low-resolution IR spectra (Joyce 1998) as well as IR photometry (Dahn et al. 1977) show very faint CO bands, in favor of a low oxygen abundance. We adopted here logA(O)=5.0.

3.3. results

Abundances were first derived for C using the CH A-X and B-X bands around 3890 and 4100-4200Å (see Figure 3.3), with checks on the $^{12}$C Swan bandheads at 5160Å and 4735Å. The N abundance was estimated using the CN A-X red bands around 8000Å. Note that an increase
Fig. 2. Effect of model atmosphere changes on the Na I D line. Dots are observations; full line is the synthetic spectrum from the model atmosphere with the final abundances, including logA(Na)=2.92; dotted lines are for 2 Na abundances: 2.92 and 3.22, and a model with solar abundances scaled by $-4$ dex, except CNO which have their final value, and [$\alpha$/Fe]=0.4 (dotted line model of Fig. 1); finally, dashed lines are for Na abundances of 2.32, 2.62 and 2.92 and the model with solar abundances scaled by $-4$ dex (dashed line model of Fig. 1). The features in the observed spectrum that are not matched by our calculations are due to C$_2$.

of the derived carbon abundance would lead to a decrease of the nitrogen abundance by the same amount. The C$_2$ Swan and Phillips bands, although very strong and displaying obvious bandheads for the $^{12}$C$_2$, $^{12}$C$^{13}$C, and $^{13}$C$_2$ isotopic combinations, could not be used, because of the absence of reliable line list. The $^{12}$C/$^{13}$C isotopic ratio of 5±1, was derived using 18 $^{13}$CN lines between 7925 and 7966Å. Wavelengths of $^{13}$CN lines from the list of Plez were shifted by 0.1Å to improve the match to the observations. Figure 4 and Figure 5 show parts of these regions. The synthetic spectrum without CN lines included is also plotted. Faint lines appear in this synthetic spectrum, which seem well placed but too faint to fit the observed spectrum. These lines are low excitation C$_2$ lines from the Phillips bands, for which we don’t have a reliable line
Fig. 3. CH A-X band head. Dots are the observed spectrum. Synthetic spectra were calculated for $^{12}$C/$^{13}$C=5 (final adopted value), 9, and 20. All abundances have their final value.

Efforts to improve the situation are ongoing, as these unsaturated lines seem promising to determine the carbon abundance in stars similar to G77-61.

The impact of microturbulence is not negligible on the strong saturated lines. We could only use a handful of strong atomic lines. Most molecular lines are also somewhat saturated. We could thus not derive a microturbulence parameter from the observations. We decided to use 0.1 km/s for the following reason: in the Sun the ratio of microturbulence parameter to the maximum MLT velocity is 1.3/2.5. The MLT velocity in our C dwarf model is 0.22 km/s, reached around $\tau_{5000}=1$. Assuming the same ratio as for the Sun, which is reasonable if we suppose that microturbulence measures convective overshooting in the upper layers of the atmosphere, we find a microturbulent velocity of the order of 100 m/s, which is one order of magnitude smaller than the thermal velocity of atoms at 3000 K. Actually, convection reaches optically thin layers in the carbon dwarf models with velocities of about 100 m/s at $\tau_{5000}=0.01$, which reinforce our estimate for the microturbulence parameter. Using 1 km/s would not impact the abundances derived here very much.
Fig. 4. CN red system lines. Dots are two observed spectra, with different setups. Synthetic spectra were calculated for 3 different N abundances, logA(N)=6.32, 6.42, 6.52, and without CN lines.

Only the use of a very unlikely microturbulence parameter of the order of 2km/s or more would induce significant abundance changes, and a notably worse match to the observations.

Unblended atomic lines are rare in the spectrum of G77-61, and most are strong. The abundances we present are based on few lines, often with low excitation energies, and subject to non-LTE effects. Large errors might have occurred due to an inappropriate description of the upper layers of the stellar atmosphere. We avoided lines in regions of the spectrum where the synthetic spectra did not reproduce well enough the molecular veiling. In particular, the region below 4000Å shows numerous large absorption features, of unidentified origin. These features show up in the spectra of other cool C-rich, metal-poor stars as well, and efforts toward their identification should be made.

The abundances are presented in Table II where we use as reference solar abundances the values from Grevesse and Sauval (1998), except for C=8.41, N=7.80, and O=8.67 which we take from Allende-Prieto, Lambert & Asplund (2002a), Asplund (2003), and Asplund et al. (2004).
Fig. 5. Red system lines of $^{12}$CN and $^{13}$CN. Spectra were computed for 3 different isotopic ratios: $^{12}$C/$^{13}$C=4, 6, 9, as well as without any CN lines. The (too) faint spectral lines appearing in the latter case (dotted line) are C$_2$ lines from the Phillips transition system. The line list we use for C$_2$ is not reliable.

Fe=7.45 from Asplund et al. (2000). Our solar abundances are the same as Christlieb at al. (2004) and Cohen et al. (2004).

The uncertainties from the quality of the fit of individual lines are of the order of 0.15 dex. In some cases (K I) possible additional blends increase the uncertainty to greater values (0.3 dex or more). For Fe I (see Fig. 6), the situation is better, as 6 lines could be used, that are not resonance lines, contrary to Na, or K. The standard deviation from the 6 lines is 0.1 dex. The uncertainties quoted in Table II are estimated on this basis. They do not include any systematic error that could arise from a change of stellar parameters. The abundances derived using the model with solar abundances scaled down by 4 dex, except the alpha elements ([α/Fe]=+0.4), and the final CNO abundances, differed from the abundances quoted in Table II by 0 dex for Ca, by less than 0.1 dex for Fe, by +0.15 dex for Mg and Cr, by 0.3 dex for Mn, and 0.6 dex for Na I. At the upper limit to the $T_{\text{eff}}$ for G77-61, i.e. 4200 K, [Fe/H] becomes -3.85. This is a reasonably secure upper limit.
Table 1. Abundances derived for G77-61

| Element | log $\epsilon$(X) | error | [X/H] | [X/Fe] | wavelength (Å) |

* $^{12}$C/$^{13}$C=5±1

b The K abundance is quite uncertain: blend with CN

to the metallicity of this star. An increase of the gravity to log $g = 5.5$ reduces the Fe abundance by 0.3 dex. For Ca II, the changes are −0.1 dex when the gravity is increased to log $g = 5.5$, and +0.3 dex for an increase of T$_{eff}$ to 4200 K, while the Na I abundance rises by +0.5 dex. These values give an estimate of the systematic errors that may affect our results, not accounting for possible non-LTE effects.

4. Discussion

We have shown that G77-61 is an extremely metal poor dwarf with [Fe/H] −4.03 dex which is highly C-enhanced, having $N$(C)/$N$(Fe) 500 times the Solar ratio, so that [C/H] is −1.4 dex. There are only −10 stars known in the Galaxy with [Fe/H < −3.5 dex verified by a detailed abundance analysis$^2$. G77–61 is arguably the third most Fe-poor star known in the Galaxy today; only HE 0107–5240 is significantly more metal poor. It is interesting that many of these stars are also extremely C-enhanced$^3$; HE 0107–5240 would appear as a C-star, as does G77–61, were it a cool dwarf rather than a subgiant with a much hotter $T_{eff}$. Furthermore, G77–61 is the only star

$^2$ These are CD−38°245, CS 22162−002, CS 22885−096 and CS 22949−037, studied in detail by Norris et al. (2001), CS 22172−002, CS 22968−014 from the sample of Cayrel et al. (2004), CS 29498−043 Aoki et al. 2002a, Aoki et al. 2002b Aoki et al., 2004, BS 16545−0089 and HE 0218−2738 from the sample of Cohen et al. (2004) and HE 0107−5240, the most Fe-poor star known 2002.

$^3$ CD−38°245 is the most metal poor star known which is not extremely C-enhanced.
Results from large recent surveys of very metal poor stars (Cayrel et al, 2004 for giants, and Cohen et al, 2004 for dwarfs) have now been published. [Cohen et al. (2004)] have pointed out that the abundance ratios [X/Fe] for elements between Mg and Zn, while they may be functions of [Fe/H], are constant to within the observational error at a fixed value of [Fe/H]. They also provide evidence that this is true of most C-rich stars, ignoring the CNO elements of course. Because of the complex spectrum of G77–61 with its many strong molecular bands including C\(_2\), we could only determine abundances for a limited set of elements. These are compared with the mean abundances derived for very metal poor giants and for dwarfs with normal CNO from [Cayrel et al. (2004)] and [Cohen et al. (2004)] in Table 2. To within the errors, G77–61 appears to also show similar abundance ratios, apart from the lighter elements discussed further below. There are however discrepancies: [Mn/Fe] is \(~\)0.5 dex lower in the normal giants and dwarfs than it is in G77–61. [Cr/Fe] is more than 0.5 dex lower in the dwarfs, and 0.8 dex in the giants. The

The abundance ratios in C-rich metal poor stars, which obey the above relations for the elements between Mg and the Fe-peak, appear to float for the lighter and for the heavier elements beyond the Fe-Peak. Some extremely metal poor C-stars have large enhancements of the heavy elements, i.e. Ba, La and even Pb in some cases (see, e.g., Van Eck et al. 2003, Aoki et al., 2002c, Lucatello et al. 2003, Sivarani et al. 2004 and Cohen et al. (2004)). Those dwarfs with s-process enhancement must arise in binary systems with a more massive primary, now presumably a white dwarf, in which mass transfer has occurred. Other very metal poor C-rich stars show no enhancement of the heavy elements (see, e.g. Aoki et al. 2002c or Cohen et al. 2004). Although we only have rough upper limits to the abundance of elements heavier than the Fe peak in G77-61, it appears to be one of the latter group, with no or only modest enhancement of the heavy elements. Regarding mass-transfer, Wallerstein & Knapp (1998) conjectured that the extremely low metal-
licity of G77–61 could be due to a loss of non-volatile elements during the mass transfer. This hypothesis does not seem supported by any observation. The metallicity now determined around 1/10000 solar is not as extreme as previously believed, and the general pattern of abundances is close to other dwarfs and giants of similar metallicity. In addition, at such a high C/O ratio the dust formed would be graphite or amorphous carbon, not incorporating Mg, Ca, Fe, and other elements that condensate in e.g. silicates in O-rich environments.

With regard to the CNO elements, the general trend seen by the second author in examining the spectra of large numbers of very metal poor stars is that if C is highly enhanced, then N may be enhanced, but the range of enhancement varies significantly. On the other hand, N is never highly enhanced unless there is a substantial C-enhancement. We compare the deduced abundances for G77–61 with those of four very metal poor C-enhanced-stars in Table 3, the first of which is HE 0107–5240, the most Fe-poor star known, analyzed by Christlieb et al. (2004). There are two independent detailed abundance analyses of CS22949–037, a highly C-enhanced, extremely metal-poor giant, by Norris et al. (2001) and by Depagne et al. (2002). The agreement between them indicates the level of accuracy one can expect for stars with such complex spectra. However G77–61 is much cooler than this star, and its spectrum is correspondingly more complex. CS 22957–027 is another extremely metal poor giant with a very large C-enhancement studied by Norris, Ryan & Beers (1997) and by Aoki et al. (2002a), the results of the more recent analysis are shown in the table. CS 29498–043 (Aoki et al. 2002a) is a very metal poor giant with highly enhanced Na and Mg as well as CNO. HE 0007-1832 is a very metal poor dwarf with no enhancement of the heavy elements (Cohen et al. (2004)).

Table 3 gives an indication of the variety found among the C-rich metal poor stars. The four stars listed have $N(C)/N(N)$ ranging over more than a factor of 1000, with no obvious correlation with [Fe/H]. G77–61 and all of the comparison stars, except HE0107-5240, though presumably a giant (Christlieb et al. 2004), show low $C^{12}/C^{13}$ ratios, indicating substantial CN processing. If one ignores the CNO elements, a crucial distinction among them involves the elements just heavier than CNO, the easiest of which to detect are Na and Mg. If those elements are not enhanced, then the abnormality is confined to the enhancement of the CNO elements, and an origin involving normal processes of nucleosynthesis within stars of intermediate mass can be imagined; for example a binary scenario with no heavy element production is viable. However, if Na and Mg are enhanced, as is the case especially for CS 22949–037 and for CS 29498–043, and to a lesser extent for the other three stars, then conventional wisdom suggests that significant production of Mg and Na is not expected for intermediate mass metal-poor stars, and a supernova event is required. It is these arguments that have led to the discussion of SN with fallback models for extremely metal poor massive stars (Umeda & Nomoto (2003) and Tsujimoto & Shigeyama (2003)) where most of the lighter elements, produced in the outer zones, get ejected, but the mass cut is such that the heavier elements fall back onto the collapsed core. The abundance ratios of the ejecta can be fine-tuned by invoking mixing as well as fallback.
Table 3. Comparison of G77–61 with carbon-rich Extremely Metal Poor Stars

| Element | G77–61 | CS29498–043 | HE0107–5240 | CS22949–037 | CS22957–027 | HE0007–1832 |

However, very recent calculations by Herwig(2005) and by Karakas(2005) demonstrate that intermediate mass very low metallicity AGB stars can produce and mix to their surface substantial amounts of Na and Mg, as well as copious amounts of C and N, and a low $^{12}$C/$^{13}$C ratio due to CN processing. This eliminates the need to seek a Type II SN origin for their excesses in G77–61 and in the other stars listed in Table 3. In addition, according to Goriely & Siess(2004), the s-process efficiency may be very much reduced in low metallicity AGB stars, due to the higher temperature of the bottom of the convective zone. This could explain the class of very metal-poor carbon-rich stars without excess of heavy elements to which G77–61 seems to belong.

We may thus view the O abundance as the key to separating excesses of the light elements C, N, Na, Mg as arising from Type II SN of some kind versus binary mass transfer involving an
extremely low metallicity AGB star. In the former case, copious O should be present, while in the latter, O should not be significantly enhanced. HE0107–5240 falls into the former category, as do at least two of the comparison stars. But preliminary information regarding the O abundance in G77–61 based on the low-resolution IR spectra of Joyce (1998) is that the O abundance is low. However, Joyce ascribed the apparent weak CO both to the low metallicity of G77–61 and at least partially to suppression of near-IR molecular bands by collision-induced absorption (H₂-H₂, and to a lesser extend He-H₂). Our model atmosphere calculations with high O abundance, and including collision-induced absorption predict strong CO bands. In any case all SN models tend to produce large amounts of O, relative to C, and it is therefore crucial to determine the O abundance in G77–61 to separate the binary AGB from the SN hypothesis for the selective abundance enhancements in this extremely metal-poor dwarf carbon star. A high resolution near-IR spectrum is already in hand and results should be available in the near future.

Acknowledgements. We thank N. Christlieb for suggesting a re-investigation of this star. B. Freytag is thanked for suggesting the microturbulence estimate, and R. Cayrel and E. Josselin for useful comments. The entire Keck/HIRES user community owes a huge debt to Jerry Nelson, Gerry Smith, Steve Vogt, and many other people who have worked to make the Keck Telescope and HIRES a reality and to operate and maintain the Keck Observatory. We are grateful to the W. M. Keck Foundation for the vision to fund the construction of the W. M. Keck Observatory. The authors wish to extend special thanks to those of Hawaiian ancestry on whose sacred mountain we are privileged to be guests. Without their generous hospitality, none of the observations presented herein would have been possible. JGC is grateful to the National Science Foundation for partial support under grant AST-0205951. This publication makes use of data from the Two Micron All-Sky Survey, which is a joint project of the University of Massachusetts and the Infrared Processing and Analysis Center, funded by the National Aeronautics and Space Administration and the National Science Foundation.
