Eukaryotic cells have evolved elaborate mRNA quality control [surveillance] mechanisms to ensure that only fully processed and error-free mRNAs are translated. These quality control mechanisms operate in both the nucleus and the cytoplasm. For instance, in the nucleus, improperly processed mRNAs are degraded before they are transported to the cytoplasm (for review, see Fasken and Corbett 2005). In the cytoplasm, surveillance pathways assess the translatability of the mRNA and degrade any that have no translation termination codons [non-stop-mediated mRNA decay, NSD] or nonsense codons [nonsense-mediated mRNA decay, NMD], thereby preventing the accumulation of potentially toxic aberrant proteins [for review, see Conti and Izaurralde 2005; Fasken and Corbett 2005; Lejeune and Maquat 2005].

NMD is one of the best characterized mRNA surveillance pathways. Its importance as a protective surveillance mechanism is underscored by the fact that ~30% of inherited genetic disorders are caused by nonsense mutations or frameshifts, which generate nonsense codons [for review, see Frischmeyer and Dietz 1999; Holbrook et al. 2004]. Transcripts derived from the mutant alleles are degraded by NMD, leading in general to a recessive mode of inheritance.

NMD not only rids the cell of mRNAs containing premature translation termination codons [PTCs or nonsense codons] as a result of mutations or errors in transcription or mRNA processing, but also regulates the expression of naturally occurring transcripts that represent ~10% of the transcriptome in yeast, Drosophila, and human cells [Lelivelt and Culbertson 1999; Holbrook et al. 2004]. Transcripts derived from the mutant alleles are degraded by NMD, leading in general to a recessive mode of inheritance.

Behm-Ansmant and Izaurralde

In this regard, the association of yeast UPF1, UPF2, and UPF3 with the eukaryotic translation termination factors eRF1 and eRF3 provides a link between NMD and translation termination (Czaplniski et al. 1998; Kobayashi et al. 2004). Moreover, multiple links between NMD factors and mRNA decay enzymes have been described in different organisms. These include the interaction of yeast UPF1 with the DCP1–DCP2 decapping complex, and the localization of human SMG7 to P-bodies, discrete cytoplasmic foci where mRNA degradation enzymes localize (for review, see Baker and Parker 2004; Conti and Izaurralde 2005).

The mechanism of NMD: an overview

In all eukaryotes a premature translation termination event leads to the assembly of the surveillance complex, yet the mechanisms by which a stop codon is defined as premature and the targeted mRNA is degraded differ across species. In mammals, PTC recognition relies on splicing: Stop codons are defined as premature if they are located ~50 nucleotides [nt] or more upstream of an exon–exon junction. In contrast, PTC recognition occurs independently of exon–exon boundaries in both Drosophila and Saccharomyces cerevisiae (for review, see Conti and Izaurralde 2005; Lejeune and Maquat 2005).

Degradation of the targeted mRNA involves many of the enzymes in the general pathway for mRNA turnover including the decapping DCP1–DCP2 complex, the 5′-to-3′ exonuclease XRN1, deadenylases, and the 3′-to-5′ exonucleases of the exosome (for review, see Baker and Parker 2004). In yeast and human cells, the major decay pathway for NMD substrates is initiated by removal of the cap structure by the DCP1–DCP2 decapping complex. Following decapping, the body of the transcript is exposed to 5′-to-3′ degradation by XRN1 (Cao and Parker 2003; Chen and Shyu 2003; Lejeune et al. 2003; Mitchell and Tollervey 2003; Couttet and Grange 2004). An alternative pathway, which also contributes to the decay of PTC-containing mRNAs, relies on the accelerated deadenylation and 3′-to-5′ degradation by the exosome (Cao and Parker 2003; Chen and Shyu 2003; Lejeune et al. 2003; Mitchell and Tollervey 2003). In Drosophila, degradation of nonsense transcripts is initiated by endonucleolytic cleavage near the PTC (Gatfield and Izaurralde 2004). The resulting 5′ decay intermediate is degraded by the exosome, while the 3′ fragment is degraded by XRN1 (Gatfield and Izaurralde 2004). Thus, in this case, the mRNA fragments are degraded from the newly generated ends without being decapped or deadenylated, suggesting that, in contrast to yeast and mammals, the decapping enzymes and deadenylases may not interact with NMD effectors in Drosophila.

As a consequence of the differences in the mechanisms of PTC recognition and mRNA decay described above, the full set of proteins required for NMD must differ across species. A striking example of this is provided in mammals, where the dependence on exon–exon boundaries for PTC recognition concurs with the requirements of components of the exon junction complex (EJC) for NMD in these organisms (for review, see Lejeune and Maquat 2005). Indeed, the positions of exon–exon boundaries are communicated to translating ribosomes by the EJC, a multiprotein assembly deposited by the spliceosome 20–24 nt upstream of exon–exon junctions (Le Hir et al. 2000). Consistent with this, the EJC components Y14, MAGOH, elf4F4III, Barentsz, and RNPS1, function in NMD (Lykke-Andersen et al. 2001; Fribourg et al. 2003; Gehring et al. 2003, 2005; Ferraiuolo et al. 2004; Palacios et al. 2004; Shibuya et al. 2004). These proteins interact with mammalian UPF3, which is also loaded onto mRNAs during splicing and represents a genuine EJC component (Kim et al. 2001; Le Hir et al. 2001).

As mentioned above, in Drosophila as well as in yeast, PTC recognition occurs independently of exon–exon junctions, and although orthologs of mammalian EJC proteins (i.e., Y14, MAGOH, elf4F4III, Barentsz, and RNPS1) are conserved in Drosophila, they are not essential for NMD (Gatfield et al. 2003), suggesting that EJC components have been co-opted by the NMD machinery after the divergence of vertebrates and invertebrates. None of these proteins has orthologs in S. cerevisiae.

A trimeric UPF1:UPF2:UPF3 complex forms the conserved core of the NMD machinery

Based on several lines of evidence, a model for NMD in mammals has emerged in which UPF3 is loaded onto mRNAs during splicing, while UPF2 is thought to join the complex in the cytoplasm after export. During the first round of translation, UPF2, UPF3, and the additional EJC components are displaced by the ribosomes as they traverse the mRNA. If translating ribosomes were to encounter a stop codon upstream of an EJC, this would lead to the incomplete removal of UPF2 and UPF3 proteins from downstream mRNA sequences and to the recruitment of UPF1, probably via interactions with the eRF1–eRF3 complex (see below). The recruitment of UPF1 creates an opportunity for the assembly of the surveillance complex consisting of UPF1, UPF2, and UPF3, which triggers UPF1 phosphorylation and ultimately targets the mRNA for rapid degradation.

A key step in this model is the formation of the trimeric UPF1:UPF2:UPF3 complex, which represents the conserved core of the NMD machinery and is thought to assemble in all organisms independently of the mechanism by which PTCs are defined (for review, see Conti and Izaurralde 2005; Lejeune and Maquat 2005). Formation of the trimeric complex is supported by genetic, biochemical, and structural evidence. UPF2 interacts directly with UPF3 (Lykke-Andersen et al. 2000; Serin et al. 2001; Kadlec et al. 2004 and references therein). This interaction has been visualized at the atomic level (Kadlec et al. 2004). UPF2 consists of three MIIF4G (middle portion of elf4G) domains, while UPF3 is characterized by a canonical RNP-type RNA-binding domain (RBD) (Kadlec et al. 2004). The structure of the complex between the interacting domains of human UPF2 and UPF3b [two UPF3 paralogs exist in humans: a and b]
shows that this interaction involves the third MIF4G domain of UPF2 and the UPF3 RBD [Kadlec et al. 2004]. The conservation of the interactions and surfaces indicates that the UPF2-UPF3 complex has similar features in all organisms. UPF2 also interacts with UPF1. The UPF1-binding site has been mapped to the N- and C-terminal regions of UPF2 [He et al. 1996]. In the UPF2:UPF3 complex, these regions are likely to be accessible for interaction with UPF1, allowing the assembly of the trimeric core of the surveillance complex.

Genetic studies both in *S. cerevisiae* and *Caenorhabditis elegans* and gene knockdowns in *Drosophila* have shown that UPF1, UPF2, and UPF3 act as obligate partners in the NMD pathway, this means that the absence of any of these proteins leads to the stabilization of PTC-containing mRNAs, and thus the inhibition of the NMD pathway [Pulak and Anderson 1993; Lelivelt and Culbertson 1999; Gatfield et al. 2003]. These genetic and knockdown studies focused on a small number of reporters and the possibility that some NMD targets bypass the requirement for the formation of the trimeric complex could not be ruled out. More recently, the analysis of whole transcriptomes by gene expression profiles in cells lacking individual NMD factors also revealed that these proteins regulate the expression of a common set of transcripts in both yeast and *Drosophila* cells. Indeed, yeast strains lacking UPF1, UPF2, or UPF3 exhibit similar expression profiles [He et al. 2003]. Similarly, depletion of UPF1, UPF2, UPF3, SMG1, SMG5, or SMG6 from *Drosophila* cells results in correlated changes in gene expression [Rehwinkel et al. 2005]. In particular, cells depleted of UPF1 or UPF2 exhibit strikingly similar expression profiles [Rehwinkel et al. 2005], excluding the possibility of a UPF2-independent NMD pathway in this organism (see below).

**Alternative NMD pathways in human cells**

Gehring et al. [2005] provide evidence that, contrary to expectation, two alternative complexes can trigger NMD in human cells. Both complexes contain UPF1, but differ in their requirement for UPF2. Gehring et al. [2005] used a tethering assay to investigate the requirement for different NMD factors and EJC components to trigger mRNA decay. This assay involves the expression of NMD effectors or EJC components fused to the RNA-binding motif of the N protein of bacteriophage λ (λN protein) or to the coat protein of MS2 bacteriophage [MS2 coat protein]. These proteins will bind with high affinity to specific RNA sequences that are inserted in the 3′ UTR of a reporter mRNA (Fig. 1). When NMD factors or EJC components are artificially tethered to the reporter in this way and are positioned at least 50 nt downstream of the natural stop codon, the natural stop is perceived as premature and the mRNA is degraded. This has been shown for the NMD effectors, UPF1, UPF2, UPF3α/b, as well as for the EJC components, Y14, MAGOH, Barentsz, eIF4AIII, and RNPS1 [Lykke-Andersen et al. 2000, 2001; Fribourg et al. 2003; Gehring et al. 2003, 2005; Ferraiuolo et al. 2004; Palacios et al. 2004; Shibuya et al. 2004].

![Figure 1. The tethering assay. Proteins of interest are fused to the MS2 coat protein or to the RNA-binding motif of the λN protein. These proteins bind with high affinity to their respective binding sites inserted in the 3′ UTR of the reporter. The artificial binding of NMD factors or EJC components to the reporter elicits its degradation, provided that the tethering sites are at least 50 nt downstream of the natural stop codon.](image)

In tethering assays, NMD can be triggered by the assembly of a complex consisting of UPF1, UPF3b, Y14, MAGOH, Barentsz, and eIF4AIII [Gehring et al. 2005]. This NMD pathway is insensitive to the depletion of UPF2, but is inhibited by depletion of Barentsz or eIF4AIII. In an alternative pathway, NMD is triggered by the association of UPF1 with RNPS1 and UPF2, and is insensitive to the depletion of Barentsz or eIF4AIII (Gehring et al. 2005). These observations suggest that EJC components have not only been co-opted by the NMD machinery during evolution, but some of these components may have acquired a role similar to that of UPF2. In particular, the tetrameric complex of Y14, MAGOH, Barentsz, and eIF4AIII appears to be able to substitute for UPF2 [Gehring et al. 2005].

In agreement with the existence of a UPF2-independent NMD pathway, earlier studies by Gehring et al. [2003] showed that the requirement for UPF2–UPF3b interaction is bypassed when UPF3b is tethered to a reporter transcript. More precisely, a UPF3b mutant lacking the RBD elicits NMD in tethering assays. Together, the results reported by Gehring et al. [2003, 2005] suggest that for a subset of targets, NMD is active either in the absence of UPF2, or when the protein levels are strongly reduced.

The lack of genome-wide information on genes regulated by key components of the NMD machinery in human cells [i.e., UPF1, UPF2, UPF3a/b], left open the question of whether NMD targets that are UPF2-independent exist. Gehring et al. [2005] provide evidence for the existence of this class of targets. Analysis of gene expression profiles in cells depleted of UPF1, UPF2, RNPS1, or Barentsz allowed those authors to identify transcripts regulated by UPF1 and Barentsz, but insensitive to the depletion of UPF2, and transcripts regulated by UPF1, UPF2, and RNPS1, but insensitive to Barentsz depletion. These results strongly support the existence in human cells of alternative NMD pathways that converge at a common requirement for UPF1. Gehring et al. [2005] also identified targets regulated by both UPF2 and Barentsz, suggesting that formation of the trimeric UPF1:UPF2:UPF3 complex is required for the degradation of these targets.
A stepwise assembly pathway for the surveillance complex

Prior to its interaction with UPF3 and/or UPF2 bound to downstream EJC components, UPF1 is thought to be recruited to PTC-containing mRNAs via interactions with the release factors (eRF1 and eRF3) when premature translation termination occurs. However, until now there was no direct biochemical evidence to support this model in higher eukaryotes. Moreover, although earlier studies had shown that phosphorylation of UPF1 by SMG1 is essential for NMD (Page et al. 1999; Denning et al. 2001; Pal et al. 2001; Yamashita et al. 2001; Anders et al. 2003; Ohnishi et al. 2003; Grimson et al. 2004), the mechanism by which UPF2 and UPF3 contributed to this process, as well as the link between UPF1 phosphorylation and premature translation termination, were not defined.

In a recent report in *Genes & Development*, Kashima et al. (2006) aim to investigate the mechanism of UPF1 phosphorylation. They begin by performing immunoprecipitations from cytoplasmic human cell extracts using anti-SMG1 antibodies. Their exciting new finding is the observation that SMG1 (endogenous or ectopically expressed) coimmunoprecipitates with UPF1, UPF2, UPF3a/b, Y14, MAGOH, eIF4AIII, and SMG7 even in the presence of RNases, suggesting that these interactions are not mediated by RNA. The nuclear cap-binding protein CBP20, and the poly[A]-binding protein PABP1 are also detected in this complex, but their association is mediated by RNA and requires Y14. In contrast, the cytoplasmic cap-binding protein eIF4E is not coimmunoprecipitated. These data indicate that Y14 bridges the association of SMG1 with spliced mRNAs that are still bound to the nuclear cap-binding complex (CBC).

To identify the domains of SMG1 involved in these interactions, the authors performed immunoprecipitations with N- and C-terminal fragments of SMG1. The N-terminal domain of SMG1 (amino acids 1–2223) coimmunoprecipitates with UPF1, UPF3a, and SMG7, but fails to precipitate EJC components. The C-terminal domain of SMG1 (amino acids 2068–3657) associates with UPF1, UPF2, UPF3b, Y14, and MAGOH, suggesting that this domain mediates the interaction with EJC components. To investigate which of the SMG1 partners is more likely to interact directly with SMG1, they performed pull-down experiments with purified recombinant N- and C-terminal domains of SMG1 and in vitro translated proteins. The purified N-terminal domain of SMG1 interacts with UPF1, while the C-terminal domain interacts with UPF2, but not with UPF3a/b or other EJC components. Thus, the association of SMG1 or its C-terminal domain with UPF3b and EJC components observed in cell lysates is most likely mediated by UPF2. In agreement with this, in cells depleted of UPF2, the amount of Y14 coimmunoprecipitating with SMG1 is strongly reduced [Kashima et al. 2006]. Additional evidence for the formation of a complex between SMG1, UPF1, UPF2, UPF3b, and Y14 is obtained in coimmunoprecipitation assays using anti-Y14 or anti-UPF2 antibodies. In both cases a complex consisting minimally of UPF2, UPF3b, and Y14 is observed.

Since there is no evidence for a direct interaction between UPF2 and the EJC, Kashima et al. (2006) reasoned that UPF3b bridges this interaction. In other words, UPF2:UPF3 heterodimerization is required for the association of EJC components with SMG1. To obtain additional evidence for the requirement of UPF2:UPF3 heterodimerization, Kashima et al. (2006) made use of two previously described UPF2 mutants that disrupt the interaction with UPF3b, in particular, a mutant carrying a deletion of the third MIF4G domain of UPF2 (amino acids 711–928) [Serin et al. 2001] and a mutant in which a single glutamic acid (E858) in the third MIF4G domain of UPF2 is replaced by an arginine [Kadlec et al. 2004]. As expected, these mutants failed to coimmunoprecipitate UPF3b, but also Y14, providing further evidence to support the proposal that UPF2 interaction with Y14 is mediated by UPF3b. More importantly, overexpression of UPF2 mutants inhibits the association of Y14 with SMG1 in a dominant-negative manner, while overexpression of wild-type UPF2 has no effect. Remarkably, these UPF2 mutants inhibit NMD when overexpressed. Indeed, the half-life of a PTC-carrying β-globin mRNA reporter increased in cells expressing the UPF2 mutants, but not wild-type UPF2 protein. The half-life of the corresponding mRNA reporter lacking a PTC was not affected by the overexpression of any of these proteins.

What could be the role of the association of SMG1 with UPF1, UPF2, UPF3, and EJC components? One obvious possibility is that formation of this complex is required to trigger UPF1 phosphorylation. Using a specific antibody raised to phosphorylated UPF1, Kashima et al. (2006) show that depletion of UPF2, UPF3b, or Y14 strongly reduces the amount of the phosphorylated form of UPF1, indicating that UPF1 is, indeed, phosphorylated as a consequence of its association with UPF2, UPF3b, Y14, and additional EJC components. One implication of these results is that UPF2, UPF3b, and Y14 are all required to trigger UPF1 phosphorylation and that neither UPF3b nor Y14 can substitute for UPF2. In agreement with this, the UPF2 mutants that no longer interact with UPF3b and prevent the association of SMG1 with Y14 also decrease the phosphorylation of UPF1, providing an explanation for their inhibitory effect in NMD.

A striking result of the work of Kashima et al. (2006) is the observation that in cells depleted of UPF2 or Y14, UPF1 is not phosphorylated, but its interaction with SMG1 is stimulated. The authors reasoned that SMG1 could form a complex with UPF1 in the absence of UPF2 and EJC components, and that this complex could represent an early step in the pathway, before its association with EJC components on the mRNA. They speculate that if this were the case, the release factors may be part of this complex. They found that the association of eRF1 and eRF3 with SMG1 and UPF1 is stimulated in Y14- or UPF2-depleted cells. Similarly, a UPF1 mutant that does not interact with UPF2 (UPF1-C126S) shows increased interaction with SMG1, eRF1, and eRF3. This mutant is not phosphorylated and inhibits NMD when overex-
pressed. Finally, overexpression of a kinase inactive mutant of SMG1, which inhibits UPF1 phosphorylation in a dominant-negative manner, also stimulates the association of UPF1 with eRF1 and eRF3. These results suggest that phosphorylation of UPF1 induces the dissociation of eRF1 and eRF3.

Together, the results of Kashima et al. [2006] reveal the existence of two novel protein complexes that represent consecutive steps in the NMD pathway (Fig. 2). One complex (the SURF complex) consists of SMG1, UPF1, and the release factors eRF1 and eRF3, and a second complex consists minimally of SMG1, UPF1 UPF2, UPF3b, Y14, MAGOH, and eIF4AIII [Fig. 2]. Although Kashima et al. [2006] did not investigate the presence of Barentsz in this complex, it is likely that it is also present, as this protein forms a stable complex with Y14, MAGOH, and eIF4AIII [Ferraiuolo et al. 2004; Palacios et al. 2004; Shibuya et al. 2004; Gehring et al. 2005].

The SURF complex appears to be transient as it can be detected in cells in which UPF1 phosphorylation is inhibited. This can be done with three different approaches: by depleting UPF2 or Y14, by overexpressing UPF2 mutants that do not interact with UPF3b, or by overexpressing an inactive form of SMG1. In all three conditions, UPF1 phosphorylation is strongly reduced and the association of eRF1 and eRF3 with UPF1 and SMG1 is stimulated. Thus, SURF accumulates when the next step in the NMD pathway, the phosphorylation of UPF1, is inhibited.

What is the link between the two complexes described by Kashima et al. (2006)? They propose that SURF assembles on ribosomes stalled at a PTC (Fig. 2). The interaction of SURF with UPF2, UPF3b, Y14, and other EJC components bound to a downstream exon–exon boundary leads to the formation of a transient complex, the SURF:EJC complex, termed decay-inducing complex (DECID). DECID triggers UPF1 phosphorylation and the dissociation of eRF1 and eRF3, and gives birth to the second complex that they describe. It should be noted that DECID is inferred to exist by the authors but not isolated as a biochemical entity in their study. Nevertheless, DECID represents the most plausible transition between SURF and the SMG1–UPF1–UPF2–UPF3–EJC complex. The RNA-dependent association of CBP20 and PABP1 with these two complexes suggests that their assembly occurs on spliced mRNAs that are still bound to the nuclear CBC. The observation that the cytoplasmic cap-binding protein, eIF4E, is not present in these complexes is not an unexpected result as eIF4E-bound mRNAs are actively translated and EJC components are thought to be displaced from the mRNA by translating ribosomes [Dostie and Dreyfuss 2002].

**UPF2-independent pathway: a minor pathway for mammalian NMD?**

The existence of a complex consisting of SMG1, UPF1, UPF2, UPF3b, Y14, and additional EJC components required to trigger UPF1 phosphorylation and NMD, as shown by Kashima et al. [2006], is consistent with results in other organisms showing that UPF1 phosphorylation and NMD require the formation of a trimeric UPF1:UPF2:UPF3 complex. These results are, at first glance, more difficult to reconcile with the UPF2-independent pathway proposed by Gehring et al. [2005]. If the UPF2-independent pathway represents a major pathway,
one would expect UPF1 phosphorylation not to be affected by UPF2 depletion, as in the absence of UPF2, NMD should still be functional.

How can the differences between these studies be explained? At least a partial answer to this question could depend on the extent of the contribution of the alternative pathways to global NMD, that is, the UPF2-independent pathway could represent a minor pathway—a possibility not excluded by Gehring et al. (2005). Another possible answer may depend on the nature of the assays used in these studies, that is, tethering assay versus PTC-containing mRNA reporters, raising the question of how well the tethering assay reflects genuine NMD. It has been reported that human UPF1 can be recruited to the 3′ UTR of specific transcripts via interactions with Staufen-1 or the histone-stem-loop-binding protein and elicits mRNA decay by a mechanism distinct from that related to NMD (Kaygun and Marzluf 2005, Kim et al. 2005). In particular, these decay pathways are independent of UPF2. By analogy, other NMD factors or EJC components may have acquired roles in post-transcriptional processes distinct from NMD. In this case, the tethering assay may not always reflect the NMD pathway. The observation that a subset of endogenous transcripts is regulated by UPF1, but is insensitive to UPF2 depletion, not only provides evidence for a UPF2-independent NMD pathway, but may also reflect additional roles of UPF1 in mRNA turnover that are not related to NMD. Most importantly, eukaryotic 3′ UTRs are sites for a wide variety of post-transcriptional regulatory elements, and tethering proteins to the 3′ UTRs of transcripts may have unpredictable effects on translation and/or mRNA turnover.

On the other hand, the stabilization of PTC-containing mRNAs in cells depleted of EJC components may not reflect a direct role of these components in the NMD pathway, but secondary effects of the depletion on EJC assembly and/or translation efficiency.

In short, the studies of Gehring et al. (2005) and Kashima et al. (2006) provide important new insights into the assembly of the surveillance complex that couples changes in the phosphorylation state of UPF1 with mRNA degradation.

An extended model for mammalian NMD

The findings of Kashima et al. (2006) provide mechanistic insights into the assembly of the surveillance complex and into the steps that lead to the phosphorylation of UPF1 [Fig. 2]. Accordingly, a premature translation termination event leads to the assembly of the SURF complex on the aberrant mRNA. SURF interacts with UPF2, UPF3, and EJC components bound to a downstream exon boundary, and this interaction triggers UPF1 phosphorylation. Phosphorylated UPF1 interacts with SMG7 (probably in a complex with SMG5 and PP2A). SMG7 would then target the PTC-containing transcript for decay by a mechanism yet to be determined. The association of SMG7, SMG5, and PP2A would also trigger the dephosphorylation of UPF1, and this event might be involved in recycling of the NMD factors for another round of NMD. This model does not exclude the possibility that the requirement for UPF2 can be bypassed by a specific constellation of EJC proteins bound to a subset of targets, as indicated by the work of Gehring et al. (2005).

The model emerging from the studies of Kashima et al. (2006) ties together years of accumulated genetic, biochemical, and structural data, and although additional studies are required for a molecular understanding of the mechanism underlying NMD, this model makes testable predictions about the role of UPF1 phosphorylation in NMD.
predictions that will certainly give way to future research.

Acknowledgments

We gratefully acknowledge Niels Gehring, Matthias Hentze, and David Thomas for critical reading of the manuscript. The authors are supported by the European Molecular Biology Organization (EMBO) and the Human Frontier Science Program Organization (HFSP).
