ABSTRACT
We report on the discovery of a new member of the magnetar class, SGR J1935+2154, and on its timing and spectral properties measured by an extensive observational campaign carried out between July 2014 and March 2015 with Chandra and XMM-Newton (11 pointings).

We discovered the spin period of SGR J1935+2154 through the detection of coherent pulsations at a period of about 3.24 s. The magnetar is slowing-down at a rate of \( P = 1.43(1) \times 10^{-11} \) s s\(^{-1}\) and with a decreasing trend due to a negative \( \dot{P} \) of \(-3.5(7) \times 10^{-19} \) s s\(^{-2}\). This implies a surface dipolar magnetic field strength of \( \sim 2.2 \times 10^{14} \) G, a characteristic age of about 3.6 kyr and, a spin-down luminosity \( L_{\text{sd}} \sim 1.7 \times 10^{34} \) erg s\(^{-1}\). The source spectrum is well modelled by a blackbody with temperature of about 500 eV plus a power-law component with photon index of about 2. The source showed a moderate long-term variability, with a flux decay of about 25% during the first four months since its discovery, and a re-brightening of the same amount during the second four months.

The X-ray data were also used to study the source environment. In particular, we discovered a diffuse emission extending on spatial scales from about 1″ up to at least 1′ around SGR J1935+2154 both in Chandra and XMM-Newton data. This component is constant in flux (at least within uncertainties) and its spectrum is well modelled by a power-law spectrum steeper than that of the pulsar. Though a scattering halo origin seems to be more probable we cannot exclude that part, or all, of the diffuse emission is due to a pulsar wind nebula.

Key words: stars: neutron – stars: magnetars – X-rays: bursts – X-rays: individual: SGR J1935+2154

1 INTRODUCTION

Large observational and theoretical efforts have been devoted in the past years to unveil the nature of a sample of peculiar high-energy pulsars, namely the Anomalous X-ray Pulsars (AXPs) and
the Soft Gamma-ray Repeaters (SGRs). These objects are believed to be isolated neutron stars and powered by their own magnetic energy, stored in a super-strong field, and are collectively referred to as magnetars (Duncan & Thompson 1992; Paczyński 1992). They share similar timing properties (spin period $P$ in the 2–12 s range and period derivative $P$ in the $10^{-13}$–$10^{-11}$ s$^{-1}$ range). Their X-ray luminosity, typically $L_X \sim 10^{32}$–$10^{33}$ erg s$^{-1}$, generally exceeds the rotational energy loss rate, while the temperatures of the thermal component observed in their spectra are often higher than those predicted by models of non-magnetic cooling neutron stars. Their (surface dipolar) magnetic fields inferred from the dipolar-loss formula are generally of the order of $B \sim 10^{14}$ – $10^{15}$ G. However, recently low dipole field magnetars have been discovered, which behave as typical magnetars but with dipolar magnetic field as low as $6 \times 10^{12}$ G, i.e. in the range of normal radio pulsars (Rea et al. 2010); these sources possibly store large magnetic energy in other components of their magnetic field (Turolla et al. 2011; Rea et al. 2013).

Sporadically, magnetars emit high energy (up to the MeV range) bursts and flares which can last from a fraction of a seconds to minutes, releasing $\sim 10^{49}$–$10^{52}$ erg s$^{-1}$, often accompanied by long-lived (up to years) increases of the persistent X-ray luminosity (outbursts). These events may be accompanied or triggered by deformations or fractures of the neutron star crust and/or local/global rearrangements of the star magnetic field. The detection of these energetic events provides the main channel to identify new objects of this class.

A fundamental question about magnetars concerns their evolutionary link to their less magnetic siblings, the rotation-powered pulsars. A number of unexpected results, both from known and newly discovered magnetars, drastically changed our understanding of these objects. In 2004, while studying the emission properties of the bright X-ray transient magnetar XTEJ1810–197, the source was discovered to be a bright transient radio pulsar, the first of the class (Camilo et al. 2006). Today we know that 4 out of the about 25 known magnetars, are occasionally shining as radio pulsars in the outburst phase. All the radio “active” magnetars are characterized by a quiescent X-ray over spin-down luminosity ratio of $L_X/L_{sd} < 1$ (Rea et al. 2012).

Energetic pulsars are known to produce particle outflows, often resulting in spectacular pulsar wind nebula (PWNe) of which the Crab is the most famous example (Weisskopf et al. 2000). Magnetars are expected to produce particle outflows as well, either in quiescence or during outbursts accompanying bright bursts. Given the strong magnetic fields associated with this class of neutron stars, the idea of a wind nebula around a magnetar is thus promising. There has not been yet a confirmed detection of such a nebula, but some cases of “magnetically powered” X-ray nebulae around pulsars with relatively high magnetic fields have been suggested. A peculiar extended emission has been reported around the rotating radio transient RRAT J1819-1458 (Rea et al. 2005; Camero-Arranz et al. 2011), with a nominal X-ray efficiency $\eta_X \sim 0.2$, too high to be only rotationally powered. The authors suggested that the occurrence of the nebula might be connected with the high magnetic field ($B = 5 \times 10^{13}$ G) of the pulsar. Similarly, Younes et al. (2012) reported the discovery of a possible wind nebula around SwiftJ1834–0846, with an X-ray efficiency $\eta_X \sim 0.7$ (but see Esposito et al. 2013 for a different interpretation in terms of dust scatter).

SGR J1935+2154 is a newly discovered member of the magnetar family, and was discovered thanks to the detection of low-Galactic latitude short bursts by Swift on 2014 July 5 (Stamatikos et al. 2014). Follow-up observations carried out by Chandra on 2014 July 15 and 29 allowed us to precisely locate the source and detect its spin period ($P=3.25$ s; Israel et al. 2014) confirming that SGR J1935+2154 is indeed a magnetar. The SGR J1935+2154 position is coincident with the center of the Galactic supernova remnant (SNR) G57.2+0.8 of undetermined age and at a possible, but uncertain, distance of 9 kpc (Sun et al. 2011; Pavlović et al. 2013).

In this paper we report on the results of an XMM-Newton and Chandra observational campaign covering the first 8 months of SGR J1935+2154’s outburst. Our observational campaign is ongoing with XMM-Newton, and its long-term results will be reported elsewhere. We also report upper limits on the radio emission derived from Parkes observations (Burgay et al. 2014). We first report on the data analysis, then summarize the results we obtained for the parameters, properties and environment of this new magnetar. Finally we discuss our findings in the context of the magnetar scenario.

## 2 X-RAY OBSERVATIONS

### 2.1 Chandra

Chandra observations of SGR J1935+2154 were carried out three times during July and August 2014 (see Table 1) in response to the detection of short SGR-like bursts from the source. The first dataset was acquired with the ACIS-S instrument in Faint imaging (Timed Exposure) and 1/8 subarray mode (time resolution: $\sim 0.44$ s), while the subsequent two pointings were obtained with the ACIS-S in Faint timing (Continuous Clocking) mode (time resolution 2.85 ms).

The data were reprocessed with the Chandra Interactive Analysis of Observations software (CIAO, version 4.6) using the calibration files available in the Chandra CALDB 4.6.3 database. The scientific products were extracted following standard procedures, but adopting extraction regions with different size in order to properly

| Mission / Obs. ID | Instrument | Date | Exposure (ks) |

* Data collected in continuous clocking mode (CC).
subtract the underlying diffuse component (see Section 3.2 and Figure [I]). Correspondingly, for the first observation (Faint imaging) we used circular regions of 1.5" (and 3.0") radius for the source (and diffuse emission) associated to a background annular region with 1.6" and 3.0" (10", 15") for the inner and outer radius, respectively. Furthermore we used rectangular boxes of 3" × 2" (and 4" × 2") sides aligned to the CCD readout direction for the remaining two observations in CC mode. For the background we used two rectangular boxes of 1.5" × 1.5" (and 2" × 2") at the sides of the source extraction region. For the spectra, the redistribution matrices and the ancillary response files were created using SPECEXTRACT. For the timing analysis, we applied the Solar system barycentre correction to the photon arrival times with Axbary.

### 2.2 XMM-Newton

XMM-Newton observations of SGR J1935+2154 were carried out between September and March 2015 (see Table [1]) to monitor the source decay and study the source properties. We used the data collected with the European Photon Imaging Camera (EPIC), which consists of two MOS ([Turner et al. 2001]) and one pn ([Strüder et al. 2001]) CCD detectors. The raw data were reprocessed using the XMM-Newton Science Analysis Software (SAS, version 14.0) and the calibration files in the ccf release of 2015 March. The pn operated in Full Window (time resolution of about 73 ms) while the MOSs were set in Small Window (time resolution of 300 ms), therefore optimized for the timing analysis. The intervals of flaring background were located by intensity filters (see e.g. [De Luca & Molendi 2004]) and excluded from the analysis. Source photons were extracted from circles with radius of 40". The pn background was extracted from an annular region with inner and outer radii of 45" and 90", respectively (also in this case the choice was dictated by the diffuse emission component; Section 3.4 and Figure [I]). Photon arrival times were converted to the Solar system barycenter using the SAS task BARYCENT using the source coordinate as inferred from the Chandra pointings (see Section 2.1). The ancillary response files and the spectral redistribution matrices for the spectral analysis were generated with ARFGEN and RMFGEN, respectively. In order to maximize the signal to noise ratio we combined, when needed, the spectra from the available EPIC cameras and averaged the response files using EPICSCPEXCOMBINE. In particular, the latter command was routinely applied for the study of the dim diffuse emission.

### 2.3 Swift

The Swift X-Ray Telescope (XRT) uses a front-illuminated CCD detector sensitive to photons between 0.2 and 10 keV ([Burrows et al. 2005]). Two readout modes can be used: photon counting (PC) and windowed timing (WT). The PC mode provides images and a 2.5 s time resolution; in WT mode only one-dimensional imaging is preserved with a time resolution of 1.766 ms. Data were processed with XRTPipeline (version 12), and itered and screened with standard criteria, correcting for effective area, dead columns, etc. Events were extracted from a 20 pixel radius region around the source position. For spectroscopy we used the spectral redistribution matrices in CALDB (20130101, v014 for the PC), while the ancillary response les were generated with XRTMKARF.

### 3 ANALYSIS AND RESULTS

#### 3.1 Position

We used the Chandra ACIS-S observation carried out on 2014 July the 15th, the only one in imaging mode, in order to precisely locate SGR J1935+2154. Only one bright source was detected in the S7 CCD operating at 1/8 of the nominal field of view. The refined position of the source, calculated with WAVEDECT, is R.A. = 19"34′′.55′′.5978s, Dec. = +21°53′′.47′′.7864 (J2000.0; statistical uncertainty of 0.′′02) with a 90% confidence level uncertainty radius of 0.′′7. This position is consistent with that of SGR J1935+2154 obtained by Swift: R.A. = 19°34′′.55′′.68s, Dec. = +21°53′′.48′′.2, J2000.0, radius of 2′′3 at 90% confidence level ([Cumings et al. 2014]). Correspondingly, we are confident that the source we detected in the Chandra image is indeed the source first detected by Swift BAT and later by XRT and responsible for the observed SGR-like bursts.

#### 3.2 Spatial analysis

Upon visual inspection of the X-ray images, it is apparent that SGR J1935+2154 is embedded in a patch of diffuse emission. To assess this in detail, we built for each pn observation a radial profile in the 0.4–10 keV band and fit a point spread function (approximated by a King model, [Read et al. 2011]) to it. In each instance, the inner part of the profile can be fit by a King model with usual core radius and slope values, whereas at radii ≈30–40′′ the data start to exceed significantly the model prediction. Since we obtained consistent results from all the 2014 observations, we repeated the same analysis on the stacked images in order to improve the signal-to-noise ratio of the data. We also selected the photons in the 1–6 keV energy range, since the spectral analysis (see Section 3.4) shows that the diffuse emission is more prominent in this band. The combined 2014 XMM-Newton profile is shown in black in Fig. [I]. The diffuse emission emerges at ≥30″ from SGR J1935+2154 and extends to at least 70″. It is however not possible to determine where the feature ends, because of both the low-signal to noise at large distance from the point source and the gaps between the CCDs. The profile of the latest XMM-Newton dataset has been obtained separately from the remaining datasets in order to look for shape variabilities of the diffuse component on long timescales. The two pn profiles are in agreement within the uncertainties (determined by using a Kolmogorov–Smirnov test that there is a substantial probability (≥50%) that the two profiles have been extracted from the same distribution), though a possible shift of the diffuse component, towards larger radii, might be present in the 30″-40″ radius interval.

A similar analysis was carried out by using the longest Chandra dataset. Though the latter is in CC mode, the field is not particularly crowded and only faint point-like objects are detected in the field of view. Correspondingly, it is still possible to gather information over smaller scales than in the XMM-Newton data. The ACIS-S PSF was simulated using the Chandra Ray Tracer (ChRT) and Model of AXAF Response to X-rays (MARX v5.0.0-0) software package. The result of this analysis is shown in blue in Figure [I]. Diffuse emission is clearly present in the Chandra data and starts becoming detectable at a distance of >1″ from the source. Due to poor statistics we have no meaningful information at radii larger than 1″.

---

1 For more details on the tasks see http://cxc.harvard.edu/chart/index.html and http://space.mit.edu/cxc/marx/index.html
than $\sim 15''$. Therefore, we are not able to assess if the diffuse structures detected by XMM-Newton and Chandra are unrelated to each other or linked somehow.

### 3.3 Timing analysis

The 0.5-10 keV events were used to study the timing properties of the pulsar. The average count rate obtained from Chandra and

\[
\begin{array}{ll}
\text{Epoch } T_0 (\text{MJD}) & 56926.0 \\
\text{Validity range (MJD)} & 56853.6 - 56976.4 \\
\dot{P}(T_0) (\text{s}) & 3.2450650(1) \\
\dot{P}(T_0) (\text{s}^{-1}) & 1.43(1) \times 10^{-11} \\

\end{array}
\]

\[B_p \, (\text{Gauss}) = 2.2 \times 10^{14} \]

\[\tau_c \, (\text{yr}) = 3600 \]

\[L_{\text{rad}} \, (\text{erg s}^{-1}) = 1.7 \times 10^{34} \]

\[XMM-\text{Newton} \text{was} \ 0.11 \pm 0.02 \, \text{cts s}^{-1} \text{and} \ 0.21 \pm 0.01 \, \text{cts s}^{-1}, \text{respectively.} \]

### Table 2. Timing results.

A refined value of $P=3.2449786(6) \, s$ (1 $\sigma$ confidence level; epoch 56866.0 MJD) was inferred based on a phase-coherent analysis. Due to the long time elapsed between the epoch of the first period determination and those of the other Chandra observations we were not able to further extend the timing solution based on the Chandra data. Therefore, we inferred a new phase-coherent solution by means of the seven XMM-Newton pointings carried out between the end of September and mid November 2014 (red filled circles in left panel of Figure 2). The new solution also included a first period derivative component: $P=3.2450650(2) \, s$ and $\dot{P}=1.373(3) \times 10^{-11} \, s^{-1}$ (1 $\sigma$ confidence level; epoch 56926.0 MJD; $\chi_i^2$ of 3.1 for 4 degree of freedom).

The latter timing solution was accurate enough to include the previous Chandra pointings (black filled circles in left panel of Figure 2). The final timing solution, encompassing the whole dataset, is reported in Table 2 and includes a second period derivative acting in the direction of decelerating the rate of period change $\dot{P}$. The inclusion of the new $P$ component has a F-test probability of $8 \times 10^{-4}$ and $10^{-7}$ of not being needed (when considering only the XMM-Newton datasets or the whole ten pointings in the fit, respectively). Moreover, the new timing solution implies a r.m.s. variability of only 55 ms, corresponding to a timing noise level of less than 2%, well within the value range observed in isolated neutron stars.

We note that the second period derivative we found is unlikely to result from a change, as a function of time, of the pulse profiles, which are almost sinusoidal and show no evidence for variation (see right panel of Figure 2).

We notice that this analysis is valid under the assumption that the location and geometry of the emitting region remains constant throughout the observations, as suggested by studies of other transient magnetars (see Perna & Gotthelf 2008; Albanese et al. 2010).

The accuracy of the timing solution is not good enough to coherently include the March 2015 XMM-
Newton data. Correspondingly, we inferred the period for this latest pointing similarly to what reported above finding a best value of $P = 3.241528(6)$ s (95% confidence level; epoch 57106.0 MJD). This is less than 2σ away from the expected period extrapolated from the timing solution in Table 2. The pulse profile parameters changed significantly with respect to the previous datasets with a pulsed fraction of only 5±1% (1σ) and a more asymmetric shape.

### 3.4 Spectral analysis

For the phase-averaged spectral analysis (performed with XSPEC 12.8.2 fitting package; Arnaud 1996), we started by considering all the datasets together. Then, we concentrated on the 29 July 2014 data, being the longest and highest statistics Chandra pointing (about 75ks effective exposure for 8200 photons) and the XMM-Newton pn spectra (effective exposure time of about 105ks and 22000 events). A summary of the spectral fits is given in Table 3. To account for the above reported diffuse component (see Section 3.2), we used, as background spectra of the point-like central source, the regions we described in Section 2.1 and 2.2 and from which we extracted later the diffuse component spectra.

We started by fitting all the 10 datasets carried out during 2014 separately leaving free to vary all the parameters. The absorption was forced to be free but the same among observations. Photons having energies below about 0.8 keV and above 10 keV were ignored, owing to the very few counts from SGR J1935+2154 (energy channels were rebinned in a way of having at least 30 events). Furthermore, all the energy channels consistent with zero after the background subtraction were ignored. The abundances used were those of Wilms et al. (2000). The spectra were not fitted well by any single component model such as a power-law (PL) or blackbody (BB) which gave a reduced $\chi^2$ in the 1.2 – 1.8 range depending on the used single component (282 and 407 degrees of freedom, hereafter d.o.f., for the Chandra and XMM-Newton spectra, respectively). A canonical two-component model often used to model magnetars, i.e. an absorbed BB plus PL, resulted in a good fit with reduced $\chi^2$ of 0.99 (280 d.o.f.) and 1.03 (405 d.o.f.) for the Chandra and XMM-Newton spectra, respectively. The inclusion of a further spectral component (the BB in the above procedure) was evaluated to have a formal F-test probability equal to 4.5 $\sigma$ and 7.0 $\sigma$ (for Chandra and XMM-Newton, respectively) of being significant.

A flux variation, of the order of about 25%, was clearly detected between the Chandra and XMM-Newton 2014 pointings. On the other hand no significant flux variation was detected among spectra of XMM-Newton observations. Correspondingly, in order to increase the statistics we proceeded to combine the seven XMM-Newton 2014 spectra together (we used the SAS task EPICSPEC-COMBINE). By using the latter spectrum we obtain a F-test probability of 7.8 $\sigma$ that the BB component inclusion is significant. In the upper panel of Figure 3 the XMM-Newton combined source spectrum (in black) is reported together with the Chandra spectrum of the longest pointing (in red; the two further Chandra spectra are not shown in Figure for clarity purposes). We note that, within about 1 $\sigma$ uncertainties, the Chandra and XMM-Newton spectral parameter are consistent with each other with the exception of the flux.

The latest XMM-Newton pointing, carried out in March 2015, was not combined with the previous ones in order to look for spectral variability on long time scales. While the PL plus BB spectral decomposition holds also for this dataset, the flux significantly increased by about 25% reaching a level similar to that of the longest Chandra pointing in July 2014. It is evident from Table 4 that the only significantly changed parameter is the flux of the PL component.

Due to the poor statistics of the Swift XRT spectra we only inferred the 1-10keV fluxes by assuming the PL plus BB model.

---

**Figure 2.** Left: SGR J1935+2154’s phase evolution as a function of time fitted with a a linear plus a quadratic plus a cubic components (upper panel). The residuals with respect to our best phase-coherent solution are reported in the lower panel, in units of seconds. Black and red dots mark the Chandra and XMM-Newton observations, respectively. Right: Chandra plus XMM-Newton background-subtracted pulse profiles (arbitrary shifted on the y-axis). From top to bottom they refer to: (a) 0.5–1.5 keV, (b) 1.5–2.0 keV, (c) 2.0–3.0 keV, (d) 3.0–12.0 keV and (e) 0.5–12.0 keV. The dashed orange curve marks the best fit (by assuming a model with two sinusoids) of profile (a): a systematic shift towards smaller phases (advance in time) as a function of energy is evident. Profile (f) has been obtained by aligning profiles from (a) to (d).
obtained by the combined XMM-Newton spectrum and including a scale factor which was free to vary in order to track the flux variation through the outburst. The lower panel of Figure 3 includes all the 1-10keV observed fluxes inferred from the Swift, Chandra and XMM-Newton spectra. It is evident that the source is still variable above a general decay trend.

The same background regions used to correct the EPIC pn source spectra were then assumed as a reliable estimate of the diffuse emission. For the background of the diffuse emission we considered two regions laying far away (at a distance >4′) from the pulsar and in two different CCDs obtaining similar results in both cases. We first fit all the seven spectra together. The use of one spectral component gave a relatively good fit with a reduced $\chi^2$ of 1.22 and 1.33 (107 d.o.f.) for an absorbed PL and BB model, respectively. Then we left free to vary all the parameters resulting in a reduced $\chi^2$ of 1.15 and 1.18 (95 d.o.f.) for the PL and BB model, respectively. While no improvement was achieved for the BB model the PL model appears to vary among XMM-Newton observations at about 2.0 $\sigma$ confidence level. Therefore, we conclude that there is no suggestion of variability for the diffuse emission. A combined (from the seven XMM-Newton pointings) spectrum for the diffuse emission was obtained, in a way similar to that already described for the source spectrum. The XMM-Newton combined spectrum of the diffuse emission and the results of the spectral fitting for the PL model are shown in Figure 3 and in Table 3. Two facts can be immediately evinced: a simple model is not a good approximation for the diffuse emission and the absorbing column is significantly different from the one we inferred for the magnetar. At present stage we cannot exclude that the two things are related to each other. In particular, we note that the largest values of the residuals originated from few “random” datapoints rather than by an up-and-down trend (often suggesting a wrong adopted continuum component; see blue points in the lower panel of Figure 3). Also for the diffuse emission we kept separated the 2015 XMM-Newton observation in order to look for spectral variations. Unfortunately, the low statistics prevented us in checking if changes in the spectral parameters are present. The inferred 1-10keV observed flux is $(1.67\pm0.08)\times10^{-11}$ erg cm$^{-2}$ s$^{-1}$, in agreement with the 2014 value.

3.5 Pre-outburst observations

Swift XRT observed SGR J1935+2154 twice before its activation during the Swift Galactic plane survey (see Campana et al. 2014). The first observation took place on Dec 30, 2010 for 514 s (obsid 00045278001). SGR J1935+2154 is far off-axis (~10′) and we derived a 3 $\sigma$ upper limit of $3.2\times10^{-12}$ cts s$^{-1}$. Assuming the same spectral model of the XMM-Newton observations (see Section 3.4 and Table 3), we derive a 1-10keV luminosity of $(9.3\pm3.6)\times10^{33}$ erg s$^{-1}$ (including uncertainties in the count rate and assuming a distance of 9 kpc).

The field was also imaged during the ROSAT all-sky survey twice, but the high column density prevents any firm upper limit on the observed flux.

4 RADIO OBSERVATIONS

The first radio follow-up observations of SGR J1935+2154 were carried out on 9 and 14 July 2014 from the Ooty Radio Telescope (ORT) and the Giant Meterwave Radio Telescope (GMRT), at 326.5 and 610.0 MHz, respectively (Surnis et al. 2014). No pulsed radio emission was found down to a flux of 0.4 mJy and 0.2 mJy at 326.5 and 610.0 MHz (assuming a 10% duty cycle), respectively.

The source was observed with the Parkes radio telescope at 10-cm and 20-cm in four epochs between 1 and 3 August, shortly after the detection of X-ray pulsations (Israel et al. 2014), and again at 10-cm on 28 September, almost simultaneously with one of our XMM-Newton observations. Observations at 10-cm were obtained using the ATNF Digital Filterbanks DFB3 (used in search mode with a sampling time of 1 ms) and DFB4 (in folding mode) at a central frequency of 3100 MHz, over 1024 MHz of bandwidth. 20-cm observations were acquired using the reconfigurable digital back-end HIPSR (HI-Pulsar signal processor) with a central frequency of 1357 MHz, a 350 MHz bandwidth and a sampling time of 64 $\mu$s. Further details of the observations are summarized in Table 4.

Data were folded in 120-s long sub-integrations using the ephemeris in Table 4 and then searched over a range of periods.
Table 3. Chandra and XMM-Newton spectral results. Errors are at a 1σ confidence level for a single parameter of interest.

spanning ±1.5 ms with respect to the X-ray rate of any given observing epoch, and over dispersion measures (DM) up to 1000 pc cm$^{-3}$.

The data acquired in search mode were also blindly searched over DMs up to 1000 both for periodic signals and single dispersed pulses. The 20-cm data were searched in real time using HEIMDALL, while the 10-cm data were analysed with the package SIGPROC (http://sigproc.sourceforge.net/). No pulsed signal with a period similar to that detected in X-rays, nor single dispersed pulses were found down to a signal-to-noise ratio of 8. Table 4 lists the upper limits obtained at each epoch and frequency.

5 DISCUSSION

Thanks to an intensive Chandra and XMM-Newton observational campaign of SGR J1935+2154 covering the first 8 months since the first bursts detected by Swift/BAT, we were able to infer the main timing and spectral properties of this newly identified member of the magnetar class. In particular, we discovered strong coherent pulsations at a period of about 3.24 s in a Chandra long pointing carried out in July 2014. Subsequently, by using the XMM-Newton observations (spaced so to keep the pulse coherence among pointings) we started building a timing solution by means of a phase fitting technique. We were able to phase-connect all the 2014 Chandra and XMM-Newton datasets and we inferred both a first and second period derivative. These findings further confirm that SGR J1935+2154 is indeed a magnetar which is slowing-down at a rate of about half a millisecond per year. However, this trend is slowing-down due to a negative $\dot{P}$ (see Table 4). The accurate timing solution allowed us also to infer the dipolar magnetic field strength, an upper limit on the true pulsar age and the corresponding spin-down luminosity (under usual assumptions).

SGR J1935+2154 is a seemingly young object, $\lesssim$ 3 kyr, with a $B_p$ value ($\sim 2 \times 10^{14}$ Gauss) well within the typical range of magnetars. The X-ray emission is pulsed. The pulse shape is energy independent (within uncertainties) and it is almost sinusoidal with a ~20% pulsed fraction (measured as the semi-amplitude of the sinusoid divided by the average count rate) during 2014. It becomes less sinusoidal with a pulsed fraction of only 5% during the latest XMM-Newton observation. We detected an energy-dependent phase shift ($\sim 0.16$ cycles at maximum), with the hard photons anticipating the soft ones. This behaviour is not very common among known magnetars, 1RXS J1708–4009 being a notable exception (though with a different trend in energy; see Israel et al. 2001; Rea et al. 2005). In 1RXS J1708–4009 the shift is likely associated to the presence of a (spin phase) variable hard X-ray component extending up to at least 100 keV (Kuiper et al. 2008; Gotz et al. 2007). Similarly, the pulse profile phase shift of SGR J1935+2154 might be due to the presence of at least two distinct components (peaks) with different weight at different energies. The non detection of emission from SGR J1935+2154 at energies above 10 keV does not allow us to firmly assess the cause of the shift.

The source spectrum can be well described by the canonical two-component model often applied to magnetars, i.e. an absorbed black body plus a power-law (K-T~0.5 keV and $\Gamma$ ~2). The SGR J1935+2154 1-10 keV observed flux of $5 \times 10^{-12}$ erg cm$^{-2}$ s$^{-1}$ is among the lowest observed so far from magnetars at the beginning of their outbursts. Although it is possible that SGR J1935+2154 is indeed a magnetar which is slowing-down at a rate of about half a millisecond per year. However, this trend is slowing-down due to a negative $\dot{P}$ (see Table 4). The accurate timing solution allowed us also to infer the dipolar magnetic field strength, an upper limit on the true pulsar age and the corresponding spin-down luminosity (under usual assumptions).

Two-component model often applied to magnetars, i.e. an absorbed black body plus a power-law (K-T~0.5 keV and $\Gamma$ ~2). The SGR J1935+2154 1-10 keV observed flux of $5 \times 10^{-12}$ erg cm$^{-2}$ s$^{-1}$ is among the lowest observed so far from magnetars.
unusual properties of SGR J1935+2154 which displays both intervals of flux weakening a brightening superimposed to a slow decay. We note that the latest XMM-Newton pointing occurred less than 20 days from the Konus-Wind detection of the first intermediate flare from this source (Golenetskii et al. 2015).

A significant diffuse emission, extending from spatial scales of $\gtrsim 1''$ up to more than $1'$ around the magnetar, was clearly detected both by Chandra and XMM-Newton. Due to the use of different instruments/modes at different epochs we were not able to test if the diffuse component varied in time (as expected in the case of scattering by dust clouds on the line-of-sight) between the Chandra and XMM-Newton pointings. Among the XMM-Newton pointings the component does not change significantly. The Chandra data allowed us to sample the spatial distribution of the component only up to about $20''$ (at larger radii we are hampered by the statistics), while the lower spatial resolution of the XMM-Newton pn allowed us to detect the diffuse emission only beyond about $20''$. We do not detect any flux variation for the diffuse emission among the eight XMM-Newton pointings despite the pulsar enhancement of about 20% between October 2014 and March 2015, a result which would favour a magnetar wind nebula (MWN) interpretation. The PL model used to fit the pn spectra implies a relatively steep photon index of about 3.8 which is similar to what observed for the candidate MWN around Swift J1834−8046 (Younes et al. 2012), but at the same time is steeper than the PL photon index of SGR J1935+2154 suggesting that the dust scattering scenario might be more likely.

In Swift J1834−8046 two diffuse components have been identified: a symmetric component around the magnetar extending up to about $50''$ interpreted as a dust scattering halo (Younes et al. 2012; Esposito et al. 2013), and an asymmetric component extending up to $150''$ proposed as a wind nebula (Younes et al. 2012). The spectrum of the former component has a PL photon index steeper than that of the magnetar (which however, at variance with SGR J1935+2154, is fitted well by a single PL alone likely due to a very high absorption which hampers the detection of any soft BB), while the latter has a flatter spectrum. In order to compare the properties of the diffuse emission around Swift J1834−8046 and SGR J1935+2154, we fitted the Chandra and XMM-Newton spectra of SGR J1935+2154 with a PL alone obtaining a photon index of 4.4±0.1 and 4.3±0.1 (we used only photons in the 1.5−8.0 keV band similar to the case of Swift J1834−8046) implying that the diffuse component might have a spectrum flatter than that of the magnetar and favouring the wind nebula scenario. In the latter case the efficiency at which the rotational energy loss of a pulsar, $\dot{E}_{\text{rot}}$, is radiated by the PWN is given by $\eta = L_{X,\text{pwn}}/\dot{E}_{\text{rot}} = (0.6 × 10^{35}/1.7 × 10^{38}) \times 0.35$, not that different from what inferred from similar components around Swift J1834−8046 and RRAT J1819−1458 (Younes et al. 2012; Rea et al. 2009). Further XMM-Newton and/or Chandra observations taken at flux levels significantly different from those we recorded so far should help in settling the nature of the diffuse emission.

A search for radio pulsed emission from SGR J1935+2154 gave negative result down to a flux density of about 0.5 mJy and 70 mJy for a single pulse). It has been suggested that whether or not a magnetar can also shine as a transient radio pulsar might depend on the ratio between its quiescent X-ray luminosity and spin-down luminosity, given that all magnetars with detected radio pulsed emission have this ratio smaller than $\sim 0.3$ (Rea et al. 2012), at variance with typical radio-quiet magnetars that have quiescent X-ray luminosity normally exceeding their rotational power. Based on the coherent timing solution we inferred a spin-down luminosity of about $2×10^{34}$ erg s$^{-1}$. At the present stage it is also rather difficult to obtain a reliable value of the quiescent luminosity due to the uncertainties on the distance and the flux of the Swift pre-outburst detection. If a distance of 9 kpc is assumed, the Swift faintest flux convert to a luminosity of $5×10^{35}$ erg s$^{-1}$ which results in $L_X/L_{\text{sd}} \sim 0.25$, close to 0.3 limiting value. However, if the distance is larger and/or the quiescent flux is a factor of few larger than estimated from Swift, the source would move toward higher values of $L_X/L_{\text{sd}}$ in the "radio-quiet" region of the fundamental plane (see left panel of Figure 2 in Rea et al. 2012). Correspondingly, the non detection of radio pulsations might be not that surprising.

The uncertainty in the quiescent level of this new magnetar makes any attempt to infer its evolutionary history rather uncertain. Given the short characteristic age (a few kyrs, which is most probably representative of the true age given that no substantial field decay is expected over such a timespan), the present value of the magnetic field is likely not that different from that at the moment of birth. The above reviewed timing characteristics would then be consistent with a quiescent bolometric luminosity of the order of $\sim 5×10^{33}$ erg s$^{-1}$ (see Fig. 11 and 12 in Viganò et al. 2013), depending on the assumed magnetic field geometry and envelope composition.

Constraints on its outburst luminosity evolution can be put from general considerations (see Pons & Rea 2012; Viganò et al. 2013). If we assume that the flux derived by the pre-outburst Swift observations provides a correct estimate of the magnetar quiescence, and we rely on a distance of 9 kpc, then the source luminosity increases from a quiescent level of $L_{X,\text{qui}} \sim 7 \times 10^{33}$ erg s$^{-1}$ to a 'detected' outburst peak of $L_{X,\text{out}} \sim 4 \times 10^{34}$ erg s$^{-1}$. Such luminosity variation within the outburst (about a factor of 5) is rather small for a magnetar with a medium-low quiescent level (see Fig. 2 of Pons & Rea 2012). In particular, the outburst peak luminosity usually reaches about $L_{X,\text{out}} \sim 5 \times 10^{35}$ erg s$^{-1}$, due to the typical energies released in magnetars’ crustal fractures (about $10^{44}$–$45$ erg; Pons & Rea 2012; Perna & Pons 2011), coupled with estimates of the neutrino cooling efficiencies (Pons & Rea 2012). If there are no intrinsic physical differences between this outburst and other magnetar outbursts (see Rea & Esposito 2011), then we can foresee two possibilities to explain the relatively low maximum luminosity detected.

The first possibility is that we have missed the real outburst peak of SGR J1935+2154, which was then caught already during its outburst decay. In this case the quiescent luminosity claimed by the archival Swift observation might be correct, and the magnetar had a flux increase during the outburst, but we could catch it only thanks to an SGR-like burst detected when the magnetar had already cooled down substantially. Given the typical outburst cooling curves, we can roughly estimate that in this scenario we observed the source about 10−40 days after its real outburst onset.

The second possibility is that the source distance is farther than the assumed SNR distance of 9 kpc (note that the method used by Pavlovic et al. 2013 to infer this distance implies a relatively large degree of uncertainty, even a factor of two in both directions). To have an outburst peak luminosity in line with other magnetars, SGR J1935+2154 should have a distance of $\sim 20\text{−}30$ kpc. At this distance the assumed Swift quiescence level would also be larger ($\sim 7 \times 10^{34}$ erg s$^{-1}$), hence a factor of $\sim 5$ in increase in luminosity in the outburst would then be in line with what observed (and predicted) in other cases (see again Fig. 2 of Pons & Rea 2012). However, in the direction of SGR J1935+2154 the Galaxy extends until $\sim 14$ kpc (Hou et al. 2009) making such a large distance rather unlikely.
We then suggest that the very low peak flux of the detected outburst of SGR J1935+2154 has no different physics involved with respect to other magnetar outbursts, but we have simply missed the onset of the outburst. If the flux detected by Swift before the outburst was its quiescent level, we envisage that the outburst onset occurred about a month before the first X-ray burst detection. If future observations will set the source at a lower quiescent level, the outburst peak should have occurred even longer before we first detected its activity.

ACKNOWLEDGEMENTS

The scientific results reported in this article are based on observations obtained with the Chandra X-ray Observatory and XMM-Newton, an ESA science mission with instruments and contributions directly funded by ESA Member States and NASA. This research has made use of software provided by the Chandra X-ray Center (CXC) in the application package CIAO, and of softwares and tools provided by the High Energy Astrophysics Science Archive Research Center (HEASARC), which is a service of the Astrophysics Science Division at NASA/GSFC and the High Energy Astrophysics Division of the Smithsonian Astrophysical Observatory. This research is based on observations with the NASA/UK/ASI Swift mission. We thank N. Schartel for approving the XMM-Newton November 2014 observation through the Director’s Discretionary Time program and the staff of the XMM-Newton Science Operation Center for performing the Target of Opportunity observations. Similarly, we thank B. Wilkes for approving the Chandra August 2014 observation through the Director’s Discretionary Time program and the Chandra staff for performing the Target of Opportunity observations. We thank the Swift duty scientists and science planners for making these observations possible. The Parkes radio telescope is part of the Australia Telescope which is funded by the Commonwealth of Australia for operation as a National Facility managed by CSIRO. The authors warmly thank Phil Edwards for the prompt scheduling of the observations and John Reynolds for releasing part of the telescope time of his project. We thanks Jules Halpern for useful comments. NR is supported by an NWO Vidi Grant, and by grants AYA2012-39303 and SGR2014-1073. This work is partially supported by the European COST Action MP1304 (NewCOMPSTAR).
