(Dated: March 23, 2022)

We study the stationary properties as well as the non-stationary dynamics of the one-dimensional partially asymmetric exclusion process with position dependent random hop rates. In a finite system of \( L \) sites the stationary current, \( J \), is determined by the largest barrier and the corresponding waiting time, \( \tau \sim J^{-1} \), is related to the waiting time of a single random walker, \( \tau_{rw} \), as \( \tau \sim \tau_{rw}^{1/2} \). The current is found to vanish as: \( J \sim L^{-z/2} \), where \( z \) is the dynamical exponent of the biased single particle Sinai walk. Typical stationary states are phase separated: At the largest barrier almost all particles queue at one side and almost all holes are at the other side. The high-density (low-density) region, is divided into \( L^{1/2} \) connected parts of particles (holes) which are separated by islands of holes (particles) located at the subleading barriers (valleys). We also study non-stationary processes of the system, like coarsening and invasion. Finally we discuss some related models, where particles of larger size or multiple occupation of lattice sites is considered.

I. INTRODUCTION

The stochastic dynamics of self-driven particles on one-dimensional lattices is one of the key problems of non-equilibrium physics. Models of this kind have been used in order to describe such different problems as e.g. highway traffic or the dynamics of motor proteins along actin filaments or microtubuli. These two examples have in common that the directed particle motion against dissipative forces is maintained by the steady input of energy, a feature that leads to the generic non-equilibrium behaviour of the system. The finite drift of the particles leads to a strong sensitivity to spatial inhomogeneities. In contrast to equilibrium systems, even a single local defect may lead to bulk effects as e.g. the separation into macroscopic low and high density domains. Moreover disorder of any type may also strongly influence the transport capacities of the system. This is in particular true for the case of strong disorder, i.e. realizations of the disorder where the local direction of the bias is non-uniform. The prototype of this kind of stochastic motion is the Sinai walk, which has been studied to great extend. The stochastic motion of a Sinai walker is characterized by large velocity fluctuations. The origin of these fluctuations is most easily understood if one translates the local hop rates into energy differences, i.e. a forward bias corresponds to a negative slope of the corresponding energy landscape and vice versa. Obviously the energy landscape is not flat for strong disorder, but characterized by barriers of different heights. The time a walker spends in front of such a barrier increases exponentially with the height of the barrier and therefore the largest barriers determine the behavior of the system.

There exists a large class of both quantum and stochastic models where the disorder plays a dominant role over deterministic fluctuations and where a connection to the Sinai walk can be made. In this respect one can mention random quantum spin chains or reaction diffusion models with quenched disorder. Besides a number of experimental setups have been identified, where this model properly describes the particle dynamics, e.g. the translocation of a RNA strand through a pore or the motion of molecular motors on microtubules.

While most of the models refer to the single particle case, more recently, the effect of strong disorder on driven-diffusive many particle systems, i.e. the so-called asymmetric exclusion process with strong disorder, has been investigated. The transport properties of the system are in close analogy to the single particle system both in the Griffiths phase, i.e. in case of a tilted energy landscape, and at the critical point, i.e. for a vanishing drift velocity of the particles. This implies that the many particle effects are most pronounced for quantities that are related to the arrangement of the particles. In case of lattice disorder, however, the transport capacity of single and many particle systems are also different, because the presence of many particles alters the effective heights of the energy barriers. A relation between the stationary current for particle disorder and for lattice disorder is announced in Ref. The article is organized as follows. The model is in-
produced in Sec III and the basic properties of the single particle motion in the framework of the concept of trapping or waiting times is given in Sec III. The stationary properties of the many particle motion is presented for non-zero average bias in Sec IV and for zero average bias in Sec V. Some related models are discussed in Sec VI and non-stationary phenomena is described in Sec VII.

In the final section of this article we will summarize and discuss our results.

II. MODEL

We consider the partially asymmetric exclusion process (PASEP) with site-dependend hop rates on a one dimensional lattice. Each lattice site \( i \) can either be empty, i.e. \( \tau_i = 0 \), or occupied by a single particle, \( \tau_i = 1 \).

The time evolution of the local configuration \((\tau_i, \tau_{i+1})\) is described by

\[
(1, 0) \rightarrow (0, 1) \quad \text{with rate } p_i, \quad (1) \\
(0, 1) \rightarrow (1, 0) \quad \text{with rate } q_i, \quad (2)
\]
i.e. particles are hopping in positive direction (from \( i \) to site \( i + 1 \)) with rate \( p_i \) and in negative direction (from site \( i + 1 \) to site \( i \)) with rate \( q_i \).

It is useful to relate the stochastic dynamics to a potential landscape by the relation

\[
\frac{q_i}{p_i} = e^{-(U_i - U_{i+1})}, \quad (3)
\]

where \( U_i \) is the energy assigned to site \( i \) (relative to a reference value, \( U_1 = 0 \)). A typical sample of this type of landscape is shown in Fig. 2. Links with backward bias \((q_i > p_i)\) correspond to a descending links of the energy landscape while those with forward bias to ascending ones. It turns out that the large scale behavior of the process is determined by the wandering properties of the energy landscape. The relation between energy landscape and system properties will be discussed in some detail in the next section.

The hop rates are independent and identically distributed random variables taken from the distributions, \( \rho(p) dp \) and \( \pi(q) dq \), respectively which will be specified later. We restrict ourselves to types of randomness where there are both forward and backward links with finite probability, i.e. the easy direction of hopping is also random. We define a control parameter as the average asymmetry between forward and backward rates as follows:

\[
\delta = \frac{[\ln p_i]_{\text{av}} - [\ln q_i]_{\text{av}}}{\text{var} \left[ \ln p_i \right] + \text{var} \left[ \ln q_i \right]}, \quad (4)
\]
such that for \( \delta > 0 \) (\( \delta < 0 \)) the particles move on average to the right (left). Here, and in the following \([\ldots]_{\text{av}}\) denotes average over quenched disorder, whereas \( \text{var}(x) \) stands for the variance of \( x \). Note, that \( \delta \sim \lim_{L \to \infty} U_L / L \), thus the control-parameter is proportional to the average slope of the potential landscape.

In most of the calculations we use a binary disorder distribution:

\[
\rho(p) = c \delta(p - 1) + (1 - c) \delta(p - r) \\
p_i q_i = r < 1 \quad \text{for all } i, \quad (5)
\]

where the control-parameter takes the value:

\[
\delta = \frac{1 - 2c}{2c(1-c) \ln r}, \quad (6)
\]

thus a biased motion to the right is realized for \( 1 \leq c < 1/2 \).

In some cases we use a power-law distribution:

\[
\rho(p) = \frac{q_{0}^{-1/D}}{D} p^{-1+1/D}, \quad \text{for } 0 < p \leq 1; \quad (7)
\]

\[
\pi(q) = \frac{q_{0}^{-1/D}}{D} q^{-1+1/D}, \quad \text{for } 0 < q \leq q_{0}
\]

where \( D^2 = \text{var} \left[ \ln p \right] = \text{var} \left[ \ln q \right] \) measures the strength of disorder and \( \delta = \ln q_{0} / (2D^2) \).

III. SINGLE PARTICLE MOTION - THE CONCEPT OF TRAPPING TIMES

We wish to introduce in the next section a simple phenomenological approach to the the biased exclusion process, which is based on the dynamics of the corresponding single-particle problem, known as Sinai walk.11,12 It is a thoroughly studied problem and here we recapitulate some of its properties which are necessary to understand to many-particle problem. For a periodic chain of length, \( L \), the stationary drift velocity, \( v_0 \), for a given realization of disorder is given by

\[
\frac{1}{v_0} = \frac{1}{\bar{L}} \sum_{i=1}^{L} \frac{1}{p_i \Pi_{i+1}} \left( 1 - \prod_{i=1}^{L} \frac{q_i}{p_i} \right)^{-1}, \quad (8)
\]

where

\[
\Pi_{i+1} = \left( 1 + \sum_{k=1}^{L-1} \prod_{j=1}^{k} \frac{q_{i+j-1}}{p_{i+j}} \right)^{-1} \quad (9)
\]

is the persistence probability25 at site \( i+1 \). This quantity measures the fraction of walks which start at site \( i+1 \) and pass the \( i, i+1 \) link first from the left, i.e. after a complete tour along the chain26.

It is clear that the regions where the particle spends long times are valleys in the energy landscape which are followed by a large barrier represented by a Brownian excursion, see the section \((\tau_i, \tau_{\delta})\) in Fig. 1. It is obvious that one can define a (single particle) trapping time for each barrier (Brownian excursion):

\[
\tau_i = \frac{1}{p_i \Pi_{i+1}}, \quad (10)
\]
of the energy landscape led to the idea of renormalizing
the energy landscape. By using the renormalization scheme and alternative approaches one obtains the same form of the trapping time distribution as given in Eq. (11).

IV. MANY PARTICLE MOTION

We now turn to the many particle case, i.e. we put
$N = O(L)$ particles on the lattice. First we consider a special form of disorder for which exact results can be derived. These are then generalized for more general form of disorder using phenomenological and scaling considerations.

A. Extreme binary disorder

Here we consider the bimodal disorder as defined in
Eq. (5) where the landscape is represented by a random walk having a step of size $\ln r$ with probability $(1 - c)$ and of size $-\ln r$ with probability $(c)$. In the limit $c \ll 1$ the walk is strongly biased, having typically downwards steps and the rare upward steps are forming the barriers. If we also have $r \ll 1$ the large barriers are typically straight, since for a large energy-scale the fluctuations are reduced. The largest barrier consists of $l_m$ upward steps, has a height of $U_m = l_m \ln r^{-1}$ and we have for the typical value $c = L = 1$. It is easy to check that the trapping time for single particle motion is $\tau_m \sim r^{l_m} \sim L^{z'}$ and the dynamical exponent $z' = \ln r / \ln c^{-1}$ corresponds to that in Eq. (13) in the given limit. Also for many par-

ticles the largest barrier plays the dominant role and we analyze first the stationary current in a system having just one large barrier of length $l_m$. This problem corresponds to a PASEP with particle in- and output against the direction of the bias. In the stationary state of this model, which is known exactly, the system is half-filled and there is a sharp front in the middle of the chain, which is the consequence of particle-hole symmetry, so

![FIG. 1: Schematic energy landscape.](image1)

![FIG. 2: Schematic form of the potential landscape for extreme disorder and the typical position of the particles. The high-density and low-density phases are separated at the middle of the largest barrier (2), the arrow indicates the height $U_m/2$. Deep valleys in the low-density phase are filled until the effective barrier is $U_m/2$ (3) and high barriers in the high-density phase are vacant above a level of $U_m/2$ (1), see text.](image2)
that particles (and holes) should overcome only an effective (filled) barrier of height $\tilde{U}_m/2$. Consequently the effective trapping time is $\tilde{\tau}_m \sim \tilde{\tau}_m^{1/2}$ and the stationary current is given by:

$$J \sim L^{-z/2}$$  \hspace{1cm} (15)

which goes to zero in the thermodynamic limit.

Now, if we consider the complete potential landscape the basic features of the above considerations remain true, since the largest barrier governs the stationary dynamics of the system. In particular in the stationary state there is a sharp front located at the middle of the largest barrier. Thus, due to particle-hole symmetry the largest barrier is half-filled and the stationary current is related to the largest effective trapping time and given by Eq. (15). The subleading barriers lead to a substructure both in the high-density and in the low-density phases, which can be related to each other by using the particle-hole symmetry. In the low-density region it is easy to see that small barriers with $\tilde{U}_i < \tilde{U}_m/2$ are completely empty, since they do not cause sufficient resistivity for the current. Only sufficiently large barriers with $\tilde{U}_i > \tilde{U}_m/2$ are able to slow down the particle and cause jams. These barriers will be filled up to the level: $\tilde{U}_i - \tilde{U}_m/2$ as a consequence of the conservation of the stationary current. The typical number of occupied barriers in the low-density phase is given by: $c_m^{1/2}L \sim L^{1/2}$. In the high-density phase due to particle-hole symmetry holes are accumulated only in such subleading barriers for which $\tilde{U}_i > \tilde{U}_m/2$. The number of holes in such a barrier scales as $\tilde{U}_i - \tilde{U}_m/2$ and the typical number of occupied barriers is $O(L^{1/2})$.

### B. General form of disorder

Next we extend our discussion to general form of disorder, when it may be still assumed that there is a sharp front separating the high-density and low-density regions. If this is the case, the front is located at a position, where the escape rate of particles and the escape rates of holes which leave the front to the left through the high-density region, are equal, which is a necessary condition for the the localisation of the front. As in the extreme disorder case, the front is located in the middle of the largest barrier. The potential landscape compared with that for extreme disorder in Fig. 2 is modified in such a way that instead of long straight lines the barriers and valleys are made by Brownian excursions.

#### 1. Distribution of the current

The typical value of the stationary current follows from the same reasoning as in Section IV A: it is given by the square root of the trapping time of a single walker at the largest barrier. Furthermore the trapping time distribution follows an asymptotically algebraic distribution given by (11).

Therefore for a given system we have to find the maximum out of $O(L)$ algebraically distributed random variables, a problem which is thoroughly studied in the mathematical literature (see e.g. in [21]) and has demonstrated to work for strong Griffiths singularities in disordered systems [22]. For our case it follows that the current is described by the well-known Fréchet distribution given by

$$P(\tilde{J}) = \frac{2}{z} \tilde{J}^{2/z-1} e^{-\tilde{J}^{2/z}},$$  \hspace{1cm} (16)

in terms of $\tilde{J} = J_0 L z^{1/2}$, where the non-universal constant $J_0$ depends on the prefactor of the tail. Thus, the current scales with the system size as given in Eq. (15).

Although the above results hold for generic hop rate distributions, a caveat is in order concerning the type of randomness. Besides the bimodal one, one may also consider hop rate distributions where the support of the forward rates, $\tilde{p}$, does not have a positive lower bound, such as for the power-law distribution in Eq. (16). In this case it may happen that the current is limited by the lowest hop rate $p_{\text{min}} \sim L^{-D}$, i.e. by a single slow link rather than by the maximal amplitude of a Brownian excursion, which is given in Eq. (15). Clearly, the exponent which enters in (15) and as well as in the scaling relation of the current is now max{z/2, D}.

For a uniform distribution with $D = 1$ the current scales as $J(L) \sim L^{-2/3}$ for $z > 2$ whereas $J(L) \sim L^{-1}$ for $1 < z < 2$. Numerical results for the distribution of the current in the anomalous region $1 < z < 2$ are shown in Fig. 3 whereas numerical results for the bimodal randomness, for which the anomalous scenario never sets in, can be found in Ref. [10]. In what follows we assume that $z/2 > D$ always holds and the current is controlled by an extended region.

![FIG. 3: The distribution of the current, calculated with uniform randomness with $q_0 = 1/3$, where $z = 1.335$. The number of samples is 10000. The solid line is the Fréchet distribution given in (11).](image-url)
2. Density profile

The density profile for general form of disorder has the same qualitative features as for the extreme disorder in Sec. IV A. The system consists of a high-density phase, where all the lattice sites are typically occupied, and of a low-density phase in which all the lattice sites are typically vacant. The front separating the two phases is just at the middle of the largest barrier. In the low-density phase only the large valleys with $U_l \geq U_{m/2}$ are filled to a level $U_l - U_{m/2}$. Similarly, in the high-density phase only the large barriers with $U_l \geq U_{m/2}$ are only partially filled up to $U_{m/2}$.

The number of occupied valleys $n(L)$, (and the number of partially filled barriers) can be estimated from the condition, that at these barriers the single particle trapping time is larger than $1/J$, thus

$$n(L) \sim L \int_{1/J}^{\infty} p(\tau) d\tau \sim LJ^{1/z},$$

where we used 14 and the fact that, due to their finite typical extension, the number of barriers in the system is of order $L$. Keeping in mind the scaling relation of the current in 15, we obtain $n(L) \sim L^{1/2}$, in agreement with the extreme disorder case in Sec. IV A. This finding is in good agreement with numerical results shown in Fig. 5.

The length of Brownian excursions has an exponential distribution32, with a finite $\delta$-dependent characteristic value. Although, the length of the $L^{1/2}$ longest excursions is $\mathcal{O}(\ln L)^{21}$, the length of the empty domain in each of these barriers equal approximately to the half of the length of the largest barrier, so one can show that the number of particles they contain is typically finite.

![Fig. 4: Numerically calculated stationary density profile of a sample of size $L = 512$. The hop rates were generated with the bimodal distribution with $c = 0.3$ and $r = 0.5$ in Eq. 14.](image)

The total number of particles clustering behind the subleading barriers is thus of the order of $L^{1/2}$. The other $\mathcal{O}(L)$ particles must be behind the largest barrier, where a macroscopic cluster of particles is formed. According to the discussion given above, the particles can be categorized into three classes as was carried out in a similar way for the disordered zero-range process10.

Almost all particles are found at the largest barrier, forming a condensate, where the density is close to one. The length of the condensate and the number of particles in it is thus

$$N_c \sim N.$$  (18)

This region is, however, cut into sections of size $\sim L^{1/2}$ by vacant clusters, which have a finite length.

In the remaining part of the system which is of size $\sim (L - N)$, particle clusters of finite size are found, separated by a typical distance of $L^{1/2}$. Due to the small local velocity in these dense clusters, the contribution of a single particle to the current is small compared to freely moving particles, therefore we call these particles inactive. Their total number is given by

$$N_{\text{in}} \sim L^{1/2}.$$  (19)

The third class of particles, i.e. active ones, move practically freely between clusters of inactive particles. Consequently, they have a significant contribution to the current. In order to estimate the number of active particles, we notice that due to the low particle density within sections between two neighboring clusters of inactive particles the dynamics of active particles corresponds to the dynamics of a single random walker in a disordered landscape. The typical length of these sections is $\sim L^{1/2}$ and the largest trapping time of an active particle is $\sim \sqrt{\tau_1} \sim L^{z/2}$. Now if $z < 1$, the particle velocity $v$ is $L$-independent. Making use of the finite-size scaling form of the current, we obtain for the density of $\rho = J/v \sim L^{-z/2}$, which is indeed vanishing in the large $L$ limit. The total number of active particles is thus

$$N_a \sim L^{1-z/2}, \quad (z < 1).$$  (20)

For $z > 1$, the largest barrier in the empty section determines the travel time and the average velocity of particles scales according to $v(L) \sim L^{(1-z)/2}$. The density
thus scales as \( \rho = J/v \sim L^{-1/2} \), which means that typically \( \mathcal{O}(1) \) particles reside between two inactive clusters. In this case the total number of active particles is given by

\[ N_a \sim L^{1/2}, \quad (z > 1). \quad (21) \]

According to the discussion above, the distribution of interparticle distances in a finite system of size \( L \) has a finite cut-off: they have the scaling form \( \mathcal{U} \sim L^{2/2} \) for \( z < 1 \), whereas \( \mathcal{T} \sim L^{1/2} \) for \( z > 1 \).

Next, the number of particles at the second largest barrier \( n_2 \) is analyzed. The height of the 2nd largest barrier is proportional to \( \ln L \) just as the height of the largest one. For the bimodal randomness where the increments of the potential are fixed, the length of the barrier must be limited by \( \mathcal{O}(\ln L) \). On the other hand, it is generally true for types of randomness under consideration, where the current is controlled by an extended cluster of exponentially rare links. The typical value for \( \langle n_2 \rangle \) is thus \( \mathcal{O}(\ln L) \). In certain samples, however, where the single-particle trapping times \( \tau_1 \) and \( \tau_2 \) at the 1st and 2nd largest barriers, respectively, are almost degenerate, meaning that \( \tau_2 \lesssim \tau_1 \), the occupation \( \langle n_2 \rangle \) is much larger than the typical value \( \mathcal{O}(\ln L) \). We show below, that these samples give a singular contribution to the sample-averaged occupation \( \langle [n_2]_{av} \rangle \). In samples, where the two largest barriers are almost degenerate, \( n_2 \) has large-scale fluctuations and the dominant contribution to the thermal average \( \langle n_2 \rangle \) comes from the fluctuations where \( n_2 \) is much larger than its most probable value. In the latter case half-filling is realized at the 2nd barrier, leading to an escape time \( \sqrt{\tau_2} \). Not considering the improbable samples with higher degeneracies (the contribution of which has in fact the same type of singularity), the number of particles located at barriers other than the two largest ones is negligible, and the problem is reduced to an effective two-barrier process with hop rates \( \sqrt{\tau_1} \) and \( \sqrt{\tau_2} \). Taking into account, that the total number of particles is \( N \), we obtain for the thermal average

\[ \langle n_2 \rangle (\alpha) = \frac{\alpha}{1 - \alpha} - (N + 1) \frac{\alpha^{N+1}}{1 - \alpha^{N+1}}, \quad \alpha < 1, \quad (22) \]

where \( \alpha \equiv \sqrt{\tau_2/\tau_1} \), and \( \langle n_2 \rangle = N/2 \) for \( \alpha = 1 \). Using the distribution function, \( \rho(\alpha) \) we can average over realizations: \( \langle [n_2]_{av} \rangle = \int_0^1 \langle n \rangle (\alpha) \rho(\alpha) d\alpha \), which is dominated by the contribution as \( \alpha \to 1 \), where \( \rho(\alpha) \) has a finite limiting value. Keeping in mind that the maximal value of \( \langle n_2 \rangle \) is \( N/2 \), we can write

\[ \langle [n_2]_{av} \rangle \approx \int_0^{1-2/N} \frac{\alpha}{1 - \alpha} \rho(\alpha) d\alpha \sim \rho(1) \ln N. \quad (23) \]

Thus the rare samples, where the second largest trapping time can be arbitrarily close to the largest one, lead to a logarithmically diverging contribution to the sample-averaged occupation at the 2nd barrier.

### C. Low density limit

Contrary to the previous section, where the global density \( \rho = N/L \) was finite, we study here the case, where the number of particles scales as \( N \sim CL^a \) for large \( L \), with \( 0 \leq a < 1 \). This implies that the particle density is vanishing algebraically according to \( \rho(L) \sim CL^{a-1} \) as \( L \to \infty \). In this case the number of active particles may be limited by \( N \), which influences the current.

We have learned in the previous chapter, that the system has a limited capacity for storing particles, given by \( N_a + N_{ia} \), and the excess of particles is driven to the macroscopic condensate. Evidently, as long as \( N \) exceeds the capacity of the system, \( N_a + N_{ia} \), the excess particles accumulate in the condensate and the largest barrier is half filled. Consequently the current remains the same as the one observed for constant density. This is, however, no longer true if \( N \) is smaller then the capacity of the system.

For \( z > 1 \), the capacity scales as \( (N_a + N_{ia} ) \sim L^{1/2} \) according to \((21)\) and \((19)\). Thus, for \( a > 1/2 \) the current, the number of active and inactive particles are not influenced, whereas \( N_a \sim L^a \). However, if \( a < 1/2 \), the condensate vanishes, and since one can show that \( N_a \) is proportional to \( N_{ia} \) for arbitrary current, both must be proportional to \( L^a \). Therefore according to \((14)\) the current is given by \( J \sim (n(L)/L)^z \sim L^{-z(1-a)} \).

For \( z < 1 \), the capacity is dominated by \( N_a \), which scales according to \((20)\). Thus, as far as \( a > 1 - z/2 \), the number of active and inactive particles and the current agrees with the case of a finite density, whereas the size of the condensate scales as \( N_c \sim L^a \). If \( a < 1 - z/2 \), there is no condensate present in the system and the number of active particles is limited to \( N_a \sim L^a \). The density \( \rho(L) \sim \rho(L) \) according to eq. \((17)\) which is indeed a vanishing fraction of the active particles, which we have tacitly assumed. According to the latter expression, if \( z + a < 1 \), \( N_{ia} \to 0 \) as \( L \to \infty \), meaning that all particles are active.

Setting \( a = 0 \) in the scaling forms obtained for the current we recover the exact results known for the Sinai walk.

### V. ZERO AVERAGE BIAS

If the control parameter is zero \( \delta = 0 \), the average tilt of the potential landscape, and consequently the sample-averaged current is zero even for finite systems. However, as a consequence of the fluctuations of randomness, the potential landscape of a single sample of size \( L \) is tilted, having a typical slope of \( L^{-1/2} \), in accordance to central limit theorem. Therefore the quantity of interest is the magnitude of the current for a finite system.

As the symmetric point is approached \( \delta \to 0 \), both the typical length and amplitude of Brownian excursions
are diverging as $\xi \sim \delta^{-2}$ and $U_m \sim \delta^{-1}$, respectively. According to central limit theorem the typical amplitude is then of the order $L^{1/2}$, consequently the magnitude of the current vanishes rapidly with the system size as

$$-\ln |J| \sim L^{1/2}. \quad (24)$$

Since the largest excursion covers an $O(1)$ fraction of the landscape, its internal structure has to be investigated in order to get some insight into the properties of the density profile. We consider first a finite sample with $\delta l \equiv \sum_{i=1}^{L} (\ln n_i - \ln q_i) = 0$, where the potential is single-valued and the current is zero. In the stationary state of this sample the particles practically occupy the $N$ lowest-potential sites, and the clusters of occupied sites are represented by Brownian excursions. (These are not to be confused with barriers, which are excursions starting at extremal sites of the landscape.) The number of such excursions $n$ in a system of size $L$ is estimated as follows. For $\delta = 0$, the asymptotic distribution of their length is

$$p_l \sim l^{-3/2}, \quad (25)$$

thus the length of the largest one among $n$ excursions, $l_{\text{max}}$, is typically of the order $n^2$. On the other hand, $n$ is related to $L$ via $n \int_{l_{\text{max}}}^{L} p_l dl \sim L$, yielding $n \sim L^{1/2}$ and $l_{\text{max}} \sim L$. Thus, the potential landscape contains $O(L^{1/2})$ excursions and the largest one of them is macroscopic. If the landscape is tilted, but $L$ is large, one can still construct an approximate profile by cutting the landscape by a straight line, the slope of which corresponds to the tilt of the landscape. Then sites below the line are filled with particles. Since the current as well as the typical tilt of samples vanish as $L \to \infty$, the profile constructed in this way is expected to be not much different from the true stationary profile.

According to the above one expects that the distribution of interparticle distances has the asymptotics as given in (25), with a finite cut-off $O(L)$. Indeed, numerical results are in satisfactory agreement with these predictions, see Fig. 6.

VI. RELATED MODELS

In this section we shall apply the phenomenological description developed above to two generalizations of the disordered exclusion process.

A. Particles of size $d$

First, we consider a process, where the particles occupy $d \geq 1$ subsequent lattice sites whereas they take steps of unit length as before.

Obviously, the single-particle trapping time at a certain barrier, $\tau$ is independent of $d$. However, the timescale for holes to overcome the same barrier which is now filled by particles of size $d$ is proportional to $\tau^{1/d}$, since the stepwidth of the holes is given by $d$, and the effective potential difference they feel is divided by $d$. Assuming that there is a sharp front at the largest barrier, it must be located at the potential where the escape rate for particles $\tau^{-1}$ and for holes $\tau^{-1}$ is related as $\tau^{-1} = d\tau^{-1}$. Parameterizing the escape rate as $\tau^{-1} = \tau_1^{-1/b}$, where $\tau_1$ is the single-particle trapping time, we have $\tau_1^{-(b-1)/(bd)} = d\tau_1^{-1/b}$. For large $\tau_1$ this yields $b = 1 + d$, consequently the current scales as

$$J \sim L^{-z/(1+d)}, \quad (26)$$

where we made use of the scaling relation $\tau_1 \sim L^z$. Following the arguments of the previous section, similar results can be derived here, as well. For instance, the current follows a Fréchet distribution (see Fig. 7 for numerical results), and the number of inactive particles scales with the system size $L$ as

$$N_{ia} \sim L^{d/(1+d)}. \quad (27)$$

Finally, we mention, that the model with $d = 2$ is related to a PASEP in which the particles are linked, meaning that the number of empty sites between two neighboring particles can be at most one. It is easy to see that the motion of holes in this model follows the same rules as, say, the left half of $d = 2$ particles in the original model. In biological transport systems, molecular motors are often attached to a rigid backbone, where the distance between motors is limited to a finite value. Exclusion processes with linked particles may be relevant for modelling cooperative behavior in these type of systems.

B. Exclusion process with multiple occupation

Our second example is the disordered version of the generalized exclusion process, where the number of par-
particles at a given site is limited by the site independent integer \( K \geq 1 \). The top most particles at a given site jumps to one of the neighboring sites with site-dependent rates \( p_i, q_i \), provided that the occupation at the target site is smaller than \( K \). This model evidently interpolates between the exclusion process (\( K = 1 \)) and the zero-range process (\( K = N \)). Moreover, it can be roughly interpreted as an exclusion process where the size of particles, \( d \equiv 1/K \), is smaller than one.

In the stationary state of this generalized model we still expect a front at the largest barrier separating an almost fully occupied region (with \( K \) particles per site) from an almost empty region. Moreover, particle-hole symmetry holds for \( K > 1 \), as well, therefore half-filling must be realized at the largest barrier, and the current scales with the system size for any finite \( K \) as for \( K = 1 \). Numerical results for the distribution of the current are presented in Fig. 8.

One can also consider \( L \)-dependence in \( K \), such as \( K = K_0 L^k \), with \( 0 < k < 1 \), leading to a scaling of the number of inactive particles scales according to \( N_{\text{in}} \sim KL^{1/2} \sim L^{1/2+k} \). The results of the previous section concerning the low-density limit can be generalized for this case in a straightforward way.

We mention finally, that regarding the number of particles at a given site as a distance variable, the present model can be mapped to an exclusion process with particlewise disorder, for any \( K \), where the distance between neighboring particles can be at most \( K \).

\section{VII. Non-Stationary Phenomena}

\subsection{A. Coarsening}

In the following we analyse the approach to the stationary state in an infinite system. When the system is started in a homogeneous configuration, it undergoes a coarsening process in the course of which the typical size of high-density and low-density regions, \( l(t) \), is growing. The growth rate of these regions is determined by the current leading to the differential equation

\begin{equation}
\frac{dl(t)}{dt} \sim |J(l(t))|.
\end{equation}

where the current \( J(l(t)) \) is a function of the time-dependent length scale. By making use of the scaling relation of the current \( I(t) \), which is valid for \( \delta \neq 0 \) we get for large \( t \)

\begin{equation}
l(t) \sim t^{1/\zeta}, \quad \zeta = \frac{z}{2} + 1, \quad (\delta \neq 0)
\end{equation}

where \( \zeta \) is the dynamical exponent related to the coarsening. We mention that the same scaling relation has already been derived for the bimodal distribution, with \( z' \) instead of \( c \), which is therefore valid only in the \( c \to 0 \) limit. Using \( I(t) = J(t) \) and \( I(t) \), the asymptotic time dependence of the current is given by

\begin{equation}
J(t) \sim t^{-\frac{\alpha}{\lambda + \alpha}}, \quad (\delta \neq 0).
\end{equation}

When the symmetric point is approached, i.e. \( \delta \to 0 \), the exponent \( z \) given in \( I(t) \), and consequently the dynamical exponent \( \zeta \) diverges as \( \zeta \sim z \sim 1/(25/26) \). Thus, strictly at the symmetric point \( \delta = 0 \), the length scale is growing slower than any power of \( t \), a phenomenon called anomalous coarsening. Substituting the scaling relation of the current \( I(t) \) into \( I(t) \), we get the asymptotic solution \( t^{1/2}e^{c_1t^{1/2}} \sim t \), leading to

\begin{equation}
l(t) \sim \left[ \ln \left( \frac{t}{\ln t} \right) \right]^{-2}, \quad (\delta = 0)
\end{equation}

which is indeed an anomalously (logarithmically) slow growth. Using \( I(t) \), we obtain for the asymptotic time-dependence of the magnitude of the current

\begin{equation}
|J(t)| \sim \frac{\ln t}{t}, \quad (\delta = 0)
\end{equation}
It is, however, circumstantial to measure the size of dense regions in numerical simulations since they are not connected. Instead, we considered the average displacement of particles \( \langle x(t) \rangle \) as a function of time for \( \delta \neq 0 \), which is related to the current according to \( \frac{d\langle x(t) \rangle}{dt} = \frac{1}{\rho} J(t) \). Comparing this relation with (28) we see, that \( \langle x(t) \rangle \) grows in time as the length scale \( l(t) \). Results of numerical simulations shown in Fig. 9 are in good agreement with the phenomenological predictions.

![Graph](image)

**FIG. 9:** Time dependence of the average displacement of a single particle measured for different values of \( \delta \neq 0 \). Bimodal randomness was used with \( c = \frac{1}{2} \) and \( r = \frac{1}{2}, \frac{3}{4}, \frac{1}{2}, \frac{3}{4}, \frac{1}{2} \) where \( z = \frac{1}{2}, 1, 2, 3, 4 \), respectively. The size of the system is \( L = 8192 \) whereas \( N = 4096 \) and the disorder average was performed over 200 samples. The straight lines have the slope \( \frac{2}{z+1} \) for each \( z \).

We mention, that the cut-off of the interparticle distance distribution \( \overline{d}(t) \) is growing slower than \( l(t) \). If \( z < 1 \), the interparticle distances in the low-density regions of size \( l(t) \) are proportional to \( (l(t))^{z/2} \), and thus grow as \( \overline{d}(t) \sim t^{z/(2+z)} \). If \( 1 < z < \infty \), the interparticle distances in the low-density regions are proportional to \( (l(t))^{1/2} \) leading to \( \overline{d}(t) \sim t^{1/(2+z)} \).

### B. Invasion

We consider in this section an open semi-infinite lattice with entrance rate \( \alpha = 1 \), furthermore, it is assumed that the lattice is initially empty. Our interest is in the invading dynamics, i.e. the dynamics of the first particle that enters the system and the motion of the bulk of particles. This question is of practical relevance, e.g. one considers a fluid penetrating a porous medium.

First, we study how the position of the leading particle evolves in time. Apparently, it must not travel slower than a single walker since the jumps to the right are never hindered, contrary to jumps to the left. Thus, for \( z < 1 \) the first particle advances with a constant velocity. For \( z > 1 \), we consider a finite system of size \( L \), and determine the finite-size scaling of the characteristic time \( \tau_p \) needed for the first particle to reach site \( L \), as follows. The leading contribution to \( \tau_p \) comes from the trapping time at the largest barrier and at subsequent barriers. Therefore we assume that the first particle has already arrived at the largest barrier of the system. Without the other particles, the typical time to overcome the barrier would be \( \tau_1 \sim L^z \). However, during this period other particles are arriving at the barrier with rate \( O(L^{-z/2}) \) determined by the current at the half-filled largest barrier between the entrance site and leading particle. The size of the largest barrier is at most \( \sim \ln L \), so it takes at most a period of \( t \sim L^{z/2} \ln L \) until half-filling of the largest barrier is achieved. Once half-filling is realized the trapping time for the leading particle is only \( O(L^{z/2}) \), so the total trapping time at the largest barrier is at most \( O(L^{z/2} \ln L) \).

After leaving the largest barrier, the first particle advances freely until it arrives at a barrier with trapping time larger than \( \sqrt{\tau_1} \), where it is assisted in passing the barrier again by other particles. The typical time-scale to fill the barrier is determined by the current and therefore given by \( t \sim L^{z/2} \). Using the assistance of the following particles the trapping time of the first particle at the barrier is given by \( O(L^{z/2}) \). Since there are \( O(L^{1/2}) \) barriers with trapping time \( \tau > \sqrt{\tau_1} \) in a sample of size \( L \), the characteristic time for getting through the system scales in leading order as \( \tau_p \sim L^{z/2+1/2} \). Therefore in a semi-infinite system, the position of the leading particle \( \xi_p \) is expected to scale as

\[
\xi_p \sim t^{1/z_p^*}, \quad \text{with} \quad z_p^* = \frac{z + 1}{2},
\]

for \( z > 1 \), whereas \( z_p = 1 \) for \( z < 1 \).

In order to test the validity of our approach, we have checked the above results numerically by measuring the distribution of times the first particle needs to traverse a finite system. The results are in good agreement with the scaling relation \( \xi_p \), as shown in Fig. 10. For zero average bias, the exponent \( z_p \) is formally infinite and the propagation of the first particle is anomalously slow.

![Graph](image)

**FIG. 10:** Distribution of invasion times calculated for different system sizes. Bimodal randomness was used with \( c = 0.3 \) and \( r = 0.2 \), where \( z_p \approx 1.45 \). The number of samples is \( 10^4 \).

Compared to the first particle, the bulk of particles
moves slower, as we shall show below. For large times, \( t \gg 1 \), a dense particle cluster is present in the system, which extends from the entrance site to a barrier which is located at \( \xi_f(t) \) and which must be the largest barrier of the interval \([0, \xi_f(t)]\). Since this barrier is half-filled, the current it maintains is typically in the order of \( \xi_f(t)^{-z/2} \).

Through this (source) barrier particles are constantly moving to the next larger barrier to its right. The escape rate at this 2nd barrier is typically \( (2\xi_f(t))^{-z/2} \), which is a finite fraction of the filling current, therefore the domain behind it is being filled up by particles with a rate \( \sim J \sim \xi_f(t)^{-z/2} \). (Those particles which escape at the 2nd barrier meanwhile, rush forward, to the third and subsequent larger barriers spreading in the domain behind the leading particle.) After certain time the domain between the source and the 2nd barrier is completely filled, and the new position of the front is now at the 2nd barrier. Thus the growth rate of the dense cluster is proportional to the current, \( \frac{dx_f(t)}{dt} \sim J \sim \xi_f(t)^{-z/2} \), yielding that the typical position of the front scales with the time as

\[
\xi_f(t) \sim t^{1/z},
\]

with a larger dynamical exponent than that of the leading particle. In order to check this numerically we have measured the number of particles \( N(t) \) as a function of time, which is expected to grow as \( \xi_f \). Results of numerical simulations shown in Fig. 11 are in good agreement with \( z \).

\[
\text{FIG. 11: Time dependence of the average number of particles of measured for different values of } \delta \neq 0. \text{ Bimodal randomness was used with } c = \frac{1}{2}, \text{ and } r = \frac{1}{2}, \text{ where } z = 1, 2, 3, \text{ respectively. The size of the system is } L = 8192 \text{ and the disorder average was performed over 200 samples. The straight lines have the slope } \frac{1}{z+2} \text{ for each } z.
\]

VIII. DISCUSSION

In this paper we have studied the partially asymmetric exclusion process with lattice disorder and we have obtained several conjecturedly exact results both for the stationary state and for related non-stationary problems. In particular for the biased system we have shown a phase separation phenomenon where a domain wall taking place in the middle of the largest barrier separates a low- and a high-density phase. The stationary current in a large finite system goes to zero as a power-law, and the corresponding exponent is just the half of the dynamical exponent of a single random walker. We have also classified the particles, which typically belong to a macroscopic condensate. This condensate, however, is cut up by \( O(L^{1/2}) \) vacant regions of finite size, which are located at the subleading barriers of the potential landscape. These vacant regions, through the particle-hole symmetry correspond to filled deep valleys in the low-density phase, which contain the so called inactive particles. Finally, the third type of particles are the active ones, which actually carry the current in the system. We have also studied the properties of the system in non-stationary processes, such as in coarsening or in the invasion, and have shown that the scaling exponents are related to the dynamical exponent of a single random walker.

Comparing the effect of different types of disorder on the stationary behavior of the PASEP we can notice some analogies but also several differences. Both for particle and lattice disorder the stationary current is vanishing as a power-law of the size of the lattice, and the critical exponents are simple related to each other. Also the phase-separation phenomena is common for the two problems. The system with particle disorder can be treated by renormalizing the particles arriving to an effective model containing only a single particle. Renormalization for lattice disorder has only been performed for a single particle leading to a motion of the particle in a renormalized landscape. For many particles it is expected that both the landscape and the particles should be renormalized and the resulting model is still a many particle problem. The actual construction of the renormalization procedure is the purpose of future research.
