Keywords
Carbapenemase-producing organism · New Delhi metallo-β-lactamase · Osteomyelitis · Tibia fracture · Ewing sarcoma

Abstract
A 31-year-old man presented with a symptomatic tibial non-union following an open tibia fracture sustained in India. The open fracture was persistently draining for 8 months following the initial injury. The decision was made to revise his tibia fracture to promote union. Intraoperative cultures of the non-union site during the revision procedure revealed osteomyelitis caused by carbapenemase-producing *Enterobacter cloacae* which was multi-drug resistant to all antibiotics except for tigecycline. The patient was treated successfully with a tigecycline-impregnated antibiotic spacer and intravenous tigecycline with repeat bone cultures demonstrating eradication of the infection. Eight weeks into treatment (1 year from initial injury), the patient developed new pain and swelling in the adjacent proximal fibula of the limb treated.
for osteomyelitis. MRI and biopsy revealed Ewing sarcoma. The patient underwent transfemoral amputation. This report describes a management protocol of carbapenemase-resistant post-traumatic osteomyelitis with no evidence of infection recurrence.

Introduction

Tibial osteomyelitis after open tibia fractures is a well-known complication with incidences from 49.4 to 63.2% [1]. Infections caused by antibiotic-resistant bacteria are becoming increasingly problematic. Carbapenemase-producing organisms (CPOs) are a relatively new group of bacteria that are resistant to a wide spectrum of antibiotics, including the carbapenems, which are often seen as the "last line" for treating infections caused by these bacteria [2]. We present a case of tibial osteomyelitis caused by carbapenemase-producing Enterobacter cloacae that was treated with systemic tigecycline resulting in sterile intra-operative cultures and resolution of symptoms. CPO-mediated tibial osteomyelitis has not been previously reported to our knowledge.

Case Report

A 31-year-old male sustained an open tibial shaft fracture in India after a motorcycle collision. The patient underwent irrigation and debridement of the open wound with intramedullary stabilization. The patient developed purulent drainage from the skin grafting site that was treated with serial bedside debridement (Fig. 1). The patient returned to Canada for orthopaedic follow-up approximately 8 months after the injury. Radiographs demonstrated a lack of union at the fracture site (Fig. 2) with persistent pain. A work-up for infection demonstrated an elevated C-reactive protein of 44 mg/L. A septic non-union was suspected and the patient was taken to the operating room for removal of the nail, debridement and culture of the non-union, and antibiotic-impregnated polymethylmethacrylate (PMMA)-coated intramedullary nail and spacer insertion in order to treat the presumed osteomyelitis with a future induced membrane technique to address the bone loss. Vancomycin 2 g and tobramycin 3.6 g were used in the PMMA spacer and nail. Three of five bone cultures taken intraoperatively grew E. cloacae resistant to multiple antibiotics (including the antibiotics used in the construct) with the only exceptions being tigecycline, aztreonam, and colistin (Table 1). The minimum inhibitory concentration of tigecycline was 1 mg/L. The patient was treated with intravenous tigecycline 50 mg every 12 h for 4 weeks. Since the initial irrigation and debridement with antibiotic spacer/nail insertion was performed with antibiotics to which the E. cloacae was resistant, the decision was made to perform a revision procedure using PMMA containing tigecycline. Four weeks after the initial antibiotic-coated nail insertion, the previous nail and spacer were removed and a new antibiotic-coated nail and spacer containing tigecycline was inserted. Five intraoperative bone samples were taken during this revision surgery to assess the response to antibiotics, and after 14 days of culture there was no growth in any of the samples, indicating successful eradication of the infection.
During a routine post-operative visit 4 weeks after the second PMMA spacer insertion, the patient complained of a swelling around the proximal fibula and a foot drop. Radiographs revealed a permeative, “moth-eaten” appearance of the proximal fibula (Fig. 3). A gadolinium-enhanced MRI suggested a primary soft tissue or bone sarcoma (Fig. 4). The tumour was positive for CD99 (Fig. 5) and ERG, and negative for myogenin, desmin, keratin, synaptophysin, chromogranin, S100, and CD45 by immunohistochemistry. Fluorescence in situ hybridization analysis demonstrated the presence of EWSR1 and FLI1 genetic rearrangement, which confirmed the diagnosis of Ewing sarcoma. The patient underwent transfemoral amputation. At the final 12-month follow-up, the patient is doing well with no evidence of recurrence of New Delhi metallo-β-lactamase (NDM)-mediated infection or Ewing sarcoma.

Discussion

Tibial osteomyelitis and non-union are devastating complications after open tibial fractures with an incidence of 5–50% [1]. Over the past decade, there has been a worldwide emergence of bacteria that have acquired resistance to a wide spectrum of β-lactam antibiotics, rendering these antibiotics ineffective [2]. The widest range of β-lactam-resistant bacteria are the CPOs. Although fears around multi-drug-resistant gram-positive bacteria such as methicillin-resistant Staphylococcus aureus (MRSA) have been widely reported, clinical microbiologists are in increasing agreement that these CPOs pose the greatest risk to public health [3]. CPO-mediated infections have high rates of mortality of up to 50% and there are few effective antibiotics available for treatment [4].

The first case of an NDM-mediated infection occurred in 2008. NDM is now the most common carbapenemase in the Indian subcontinent with a few cases reported in North America. Osteomyelitis caused by CPO has been rarely reported in the literature. The first case of CPO-mediated osteomyelitis caused by E. cloacae was reported in 2019 [5]. This multi-drug-resistant infection was successfully treated with a hexapod frame, systemic colistin, sulbactam, and fosfomycin as well as local delivery of colistin-impregnated methanesulphonate [5]. Treatment of CPO-mediated infections remains difficult as few antibiotics exist that are effective in eradication. Most CPO infections are treated with colistin, tigecycline, and fosfomycin [2]. Despite resistance to carbapenems, some antibiotic regimens using dual carbapenem therapy may be effective due to synergistic effects [6]. Combining these various antimicrobials is more effective at reducing mortality rates than monotherapy alone [2]. Tigecycline is a minocycline-derived antibiotic which was originally approved for use in skin and intra-abdominal infections. It is parentally administered and demonstrates good activity against both gram-positive and gram-negative bacteria. Tigecycline has been previously used to treat bone and joint infections in multi-drug-resistant gram-positive bacteria [7, 8]. Intravenously administered tigecycline demonstrates good penetration into bone with high residual levels of the antibiotic in bone tissue despite being cleared rapidly in serum once the administration of the antibiotic has completed [9, 10]. Tigecycline exists as a powdered preparation and, when combined with PMMA, is heat stable and demonstrates clinically significant antibiotic elution that lasts up to a week [11]. In this case, the tissue and bone samples taken during the second surgery (after 4 weeks of intravenously administered tigecycline in isolation) did not grow...
any bacteria. This suggests that intravenous tigecycline without the need for tigecycline-impregnated cement spacers may be sufficient for eradication of infected tissue. However, it should be noted that true eradication of infection, as demonstrated by bony union, was not observed as the limb was amputated due to the Ewing sarcoma prior to signs of healing.

This is an atypical presentation for Ewing sarcoma in that the patient developed the sarcoma immediately adjacent to a soft tissue and bone infection. Ewing sarcoma is caused by a balanced translocation resulting in a fusion protein that acts as an oncogenic transcription factor [12]. Ewing sarcoma is thought not to occur as a secondary neoplasm, as the only predisposing factors are tumour syndromes. Ewing sarcoma has been known to mimic osteomyelitis, with a number of cases reported in the literature [13–17]. Interestingly, there is one other case published where a 24-year-old patient with suspected osteomyelitis subsequently developed Ewing sarcoma [18]. The patient was treated for recurring humeral shaft osteomyelitis and developed Ewing sarcoma in the humerus 3 years after the initial diagnosis of osteomyelitis [18]. As there is no association between osteomyelitis and Ewing sarcoma, the co-occurrences of these entities is likely coincidental, although unusual nonetheless.

In conclusion, health care providers should be aware of the threat of CPO-mediated orthopaedic infections and the various treatment options available for treatment. This case report highlights a treatment regimen for NDM-mediated tibial osteomyelitis using systemic tigecycline, with no evidence of infection recurrence after 6 weeks of treatment. This case is unique in the development of a Ewing sarcoma approximately 1 year after the initial injury and 8 weeks into treatment of the osteomyelitis. As the incidence of these infections increases, an understanding of effective antimicrobial and surgical therapy is essential for eradication of infection.
