Measurement of Elastic $\omega$
Photoproduction at HERA

ZEUS Collaboration

Abstract

The reaction $\gamma p \rightarrow \omega p$ ($\omega \rightarrow \pi^+\pi^-\pi^0$ and $\pi^0 \rightarrow \gamma\gamma$) has been studied in $ep$ interactions using the ZEUS detector at photon-proton centre-of-mass energies between 70 and 90 GeV and $|t| < 0.6$ GeV$^2$, where $t$ is the squared four momentum transferred at the proton vertex. The elastic $\omega$ photoproduction cross section has been measured to be $\sigma_{\gamma p \rightarrow \omega p} = 1.21 \pm 0.12 \pm 0.23 \mu$b. The differential cross section $d\sigma_{\gamma p \rightarrow \omega p}/d|t|$ has an exponential shape $e^{-b|t|}$ with a slope $b = 10.0 \pm 1.2 \pm 1.3$ GeV$^{-2}$. The angular distributions of the decay pions are consistent with $s$-channel helicity conservation. When compared to low energy data, the features of $\omega$ photoproduction as measured at HERA energies are in agreement with those of a soft diffractive process. Previous measurements of the $\rho^0$ and $\phi$ photoproduction cross sections at HERA show a similar behaviour.

1 Introduction

Elastic photoproduction of vector mesons, $\gamma p \rightarrow V p$, has been extensively studied in fixed target experiments at centre-of-mass energies up to $W \approx 20$ GeV. The production of $\rho^0$, $\omega$ and $\phi$ is usually described in the framework of the vector meson dominance model (VDM) [1] and Regge theory [2]. The $W$ dependence of the cross section can be parametrised in Regge theory by the sum of two terms, one due to Pomeron exchange and the other to Reggeon exchange. While the latter falls with $W$, the former is almost flat. Whereas $\rho^0$ and $\phi$ production is predominantly due to Pomeron exchange at all energies, the energy behaviour of $\omega$ production investigated before HERA suggests a non-negligible contribution from Reggeon exchange. It is therefore of interest to analyse $\omega$ photoproduction at HERA, where Pomeron exchange should dominate.

More specifically, it is important to establish if the features typical of elastic $\rho^0$ and $\phi$ vector meson production are also observed in $\omega$ photoproduction at high energy. Among these features are the weak dependence of the elastic cross section on $W$, the exponential shape of the differential cross section in $t$, where $t$ is the squared four momentum transferred at the proton vertex, and the observation that the vector meson retains the helicity of the photon ($s$-channel helicity conservation, SCHC). In addition, a comparison of the photoproduction cross sections of the light vector mesons $\rho^0$ [3, 4], $\omega$ and $\phi$ [5] at HERA energies allows another check of their diffractive production mechanism.

This paper reports a measurement of the photoproduction of $\omega$ mesons using the reaction $ep \rightarrow e\omega p$ with the ZEUS detector at HERA. The $\omega$ meson is observed via its decay into $\pi^+\pi^-\pi^0(\pi^0 \rightarrow \gamma\gamma)$ in the kinematic range $70 < W < 90$ GeV and $p_T^2 < 0.6$ GeV$^2$, where $p_T$ is the transverse momentum of the $\omega$ with respect to the beam axis. For these events the scattered positron was not observed in the detector, thereby restricting the photon virtuality $Q^2$ to values smaller than 4 GeV$^2$, with a median $Q^2$ of about $10^{-4}$ GeV$^2$.

2 Kinematics

Elastic $\omega$ photoproduction at HERA is measured via the reaction:

$$e(k) + p(P) \rightarrow e(k') + \omega(V) + p(P') ,$$
which is shown in Fig. 1. The symbols in brackets denote the four momentum of each particle.

At fixed \( ep \) centre-of-mass energy, the inclusive scattering of unpolarized positrons and protons can be described by any pair of the following variables: the four momentum squared carried by the photon,

\[-Q^2 = q^2 = (k - k')^2,\]

the centre-of-mass energy squared of the \( \gamma^* p \) system,

\[W^2 = (q + P)^2 = -Q^2 + 2y(k \cdot P) + M_p^2,\]

where \( M_p \) is the proton mass, and the fractional energy transfer of the positron in the proton rest frame,

\[y = (q \cdot P)/(k \cdot P).\]

Additional variables are required to describe elastic vector meson photoproduction: the squared four momentum transferred at the proton vertex,

\[t = (P - P')^2 = (q - V)^2,\]

the angle between the \( \omega \) production plane and the positron scattering plane, and the polar and azimuthal angles of the normal to the \( \omega \) decay plane in the \( s \)-channel helicity frame.

For the data discussed here, only the decay products of the \( \omega \) were measured. The value of \( Q^2 \) is restricted between the kinematic limit \( Q_{\text{min}}^2 = M_e^2 y^2 \approx 10^{-9} \text{ GeV}^2 \) and \( Q_{\text{max}}^2 \approx 4 \text{ GeV}^2 \), the latter set by the requirement that the scattered positron is not detected in the main detector. At low values of \( Q^2 \) the virtual photon is emitted with negligible transverse momentum and with longitudinal momentum \( p_{Z\gamma} \approx -E_\gamma \), where \( E_\gamma \) is the photon energy. Under these assumptions, \( t \) and \( W \) can be expressed in terms of the energy \( E \) and the longitudinal and transverse momenta \( p_Z \) and \( p_T \) of the \( \omega \) in the laboratory frame: \( W^2 \approx 2(E - p_Z)E_p \) and \( t \approx -p_T^2 \), where \( E_p \) is the proton beam energy.

In order to determine the photoproduction cross section \( \sigma_{\gamma p \rightarrow \omega p} \) from the measured electroproduction cross section \( \sigma_{ep \rightarrow e\omega p} \), the following relationship was assumed.

\[1\] The ZEUS coordinate system has positive \( Z \) in the direction of flight of the beam protons and the \( X \)-axis is horizontal, pointing towards the centre of HERA. The nominal interaction point is at \( X = Y = Z = 0 \).
based on VDM \cite{1} and on the one photon exchange approximation\footnote{The one photon exchange approximation relates the $ep$ cross section to the longitudinal and the transverse $\gamma^*p$ cross sections for $Q^2 \neq 0$, the latter being related to $\sigma_{\gamma p \to \omega p}$ by VDM.}:

$$\frac{d^2\sigma_{ep \to e\omega p}}{dydQ^2} = \Phi(y, Q^2) \cdot \sigma_{\gamma p \to \omega p}(W),$$

where

$$\Phi(y, Q^2) = \frac{\alpha^2}{2\pi Q^2} \left[ \frac{1 + (1 - y)^2}{y} - \frac{2(1 - y)}{y} \left( \frac{Q^2_{\min}}{Q^2} - \frac{Q^2}{M^2_\omega} \right) \right] \left( 1 + \frac{Q^2}{M^2_\omega} \right)^{-2}$$

is the effective photon flux and $\sigma_{\gamma p \to \omega p}$ is the photoproduction cross section.

3 Experimental conditions

3.1 HERA

During 1994, HERA operated at a proton energy of 820 GeV and a positron energy of 27.5 GeV. Typically 153 colliding positron-proton bunches were stored, along with 17 unpaired proton and 15 unpaired positron bunches. These additional bunches were used to study background from beam-gas interactions.

3.2 The ZEUS detector

A detailed description of the ZEUS detector can be found elsewhere \cite{6}. In addition to the hadron electron separator, which is described below, the main components used in this analysis are the same as those used for the 1994 $\phi$ photoproduction analysis \cite{5}. Of the latter, only the calorimeter and the tracking chambers are mentioned here.

Charged particle momenta are reconstructed from information from the vertex detector (VXD) \cite{7}, the central tracking detector (CTD) \cite{8} and the rear tracking detector (RTD) \cite{9}. The total angular coverage is $15^\circ < \theta < 170^\circ$, where $\theta$ is the polar angle in the ZEUS coordinate system.

The high resolution uranium-scintillator calorimeter (CAL) \cite{10} is divided into three parts, the forward calorimeter (FCAL), the barrel calorimeter (BCAL) and the rear calorimeter (RCAL), respectively covering the polar angle regions $2.6^\circ$ to $36.7^\circ$, $36.7^\circ$ to $129.1^\circ$, and $129.1^\circ$ to $176.2^\circ$. Each part consists of towers which are
longitudinally subdivided into electromagnetic (EMC) and hadronic (HAC) readout cells. The transverse sizes are $5 \times 20 \text{ cm}^2$ for the EMC cells ($10 \times 20 \text{ cm}^2$ in the RCAL) and $20 \times 20 \text{ cm}^2$ for the HAC cells. From test beam data, energy resolutions with $E$ in GeV of $\sigma_E/E = 0.18/\sqrt{E}$ for electrons and $\sigma_E/E = 0.35/\sqrt{E}$ for hadrons have been obtained.

The hadron electron separator (HES) \cite{11} consists of silicon detectors $400 \mu\text{m}$ thick. In the 1994 running period only the rear part (RHES) was operational. The RHES in the RCAL as seen from the interaction point is shown in Figure 2, illustrating the geometrical structure. The RHES is located in the RCAL at a depth of 3.3 radiation lengths, covering an area of about $10 \text{ m}^2$. Each silicon pad has an area of $28.9 \times 30.5 \text{ mm}^2$, providing a spatial resolution of about 9 mm for a single hit pad. If more than one pad is hit by a shower, a cluster consisting of at most $3 \times 3$ pads around the most energetic pad is considered. This allows a more precise reconstruction of the position, providing a resolution of about 5 mm for energies greater than 5 GeV. The RHES measures the energy deposited by charged particles near the maximum of an electromagnetic shower. This energy is measured in units m.i.p., the energy deposited by a minimum ionizing particle. The mean energy deposit expected for a shower induced by a 1 GeV photon is 7.6 m.i.p.

### 3.3 Trigger

The conditions of the three level trigger used in this analysis are those of the 1994 $\phi$ photoproduction measurement \cite{5}.

The requirements at the first trigger level consist of a minimum RCAL electromagnetic energy deposit of 464 MeV reconstructed by the calorimeter trigger processor \cite{12}, a maximum deposit of 1250 MeV reconstructed in the FCAL towers surrounding the beam pipe, and at least one track candidate based on CTD information.

Upstream proton-gas interactions are rejected at the second and third trigger levels using calorimeter time measurements.

The third level trigger also uses the CTD information to reject events with a reconstructed vertex more than 66 cm away from the nominal interaction point along $Z$, with more than four track candidates, or with no pair of tracks forming an invariant mass less than 1.5 GeV assuming the pion mass for each track.
4 Event selection and reconstruction

The data taken during 1994 correspond to a total integrated luminosity of about 3.2 pb$^{-1}$. After taking the trigger prescaling into account, the data presented in this analysis correspond to an effective integrated luminosity of 894 ± 13 nb$^{-1}$.

4.1 Selection criteria

The final sample of ω events was selected by imposing the following offline requirements:

- Two tracks with opposite charges associated to a common vertex and no further tracks.

- A well reconstructed π$^0$ candidate from two clusters (as defined in section 4.2) in RCAL and RHES, with at most one additional cluster, as described in detail below.

- No clusters in BCAL or RCAL with energy greater than 200 MeV and more than 20 cm away from the extrapolated position of either of the two tracks. The cut was not applied to the clusters in the RCAL associated to the π$^0$ candidate. This cut rejects events with additional neutral particles.

- Transverse momentum of each track greater than 100 MeV and polar angle $\theta \leq 165^\circ$, to restrict the data to a region of good track reconstruction efficiency.

- Total energy in FCAL less than 1 GeV, in order to limit the contamination by proton dissociative events ($\gamma p \rightarrow \omega N$).

4.2 Reconstruction of the π$^0$

For the reconstruction of the π$^0$ via the decay photon pair, signals in RCAL and RHES were separately combined into clusters.

RCAL clusters are objects consisting of adjacent calorimeter cells. For the present data, clusters were usually formed by one cell. To reject background from uranium radioactivity, a minimum cell energy of 100 MeV was required. This should be compared with the mean measured photon energy of 500 MeV with a standard deviation of 210 MeV, which is reproduced by the simulations described below.
RHES clusters consist of at most $3 \times 3$ adjacent silicon pads (see section 3.2). Most (63%) of the clusters consisted of a single pad. A cut on the signal from any RHES pad with less than 1 m.i.p. was applied to reject noise. The mean RHES signal for this data sample was 4.2 m.i.p. with a standard deviation of 2.5 m.i.p.

RHES clusters were assigned to an RCAL cluster if they were within a distance of 15 cm (measured in the RHES plane). RCAL clusters less than 20 cm away from the extrapolated impact point of a charged track were excluded, thus restricting the sample to clusters produced by neutral particles. Events with exactly two of these neutral RCAL-RHES clusters were then selected, allowing at most one additional cluster in RCAL with no corresponding RHES cluster and an energy of less than 200 MeV. These two RCAL-RHES clusters were required to have an energy deposition in the electromagnetic part of the calorimeter only. Fewer than 0.5% of the RCAL clusters were associated with more than one RHES cluster. Even less frequent were events in which the two decay photons were assigned to one RHES cluster.

Using the Monte Carlo simulations described in section 5, the energy of the RCAL clusters was corrected for losses in the material between the interaction point and the RCAL. The average correction was approximately 25%. The corrected RCAL energies and RHES position information were used to calculate the two-cluster invariant mass $M_{\gamma\gamma}$. The spectrum is plotted in Fig. 3(a). A fit with the sum of a Gaussian and a second order polynomial yields a mean of the Gaussian of $\langle M_{\gamma\gamma} \rangle = 124 \pm 1$ MeV and a standard deviation of $28 \pm 1$ MeV. The difference with respect to the $\pi^0$ mass is a consequence of the incomplete description of low energy electromagnetic showers in the Monte Carlo simulation. Events with $84 < M_{\gamma\gamma} < 164$ MeV, i.e. a mass within $1.5 \sigma$ of $\langle M_{\gamma\gamma} \rangle$, were selected.

To improve the resolution in the four momentum and invariant mass of the $\pi^+\pi^-\pi^0$ system, the invariant mass of the two photons was constrained to the $\pi^0$ mass. Since the $\pi^0$ energies are small, only large opening angles $\alpha$ between the decay photons occur. As the angle $\alpha$ is well determined due to the precise position measurement of RHES, the resolution in $M_{\gamma\gamma}$ is dominated by the energy resolution of RCAL. Thus only the energies were modified in the procedure. The modified values $E_{1\text{fit}}, E_{2\text{fit}}$ of the corrected energies $E_1, E_2$ of the RCAL clusters were determined by minimizing the quantity:

$$
\chi^2(E_{1\text{fit}}, E_{2\text{fit}}) = \frac{(E_1 - E_{1\text{fit}})^2}{\sigma_{E_1}^2} + \frac{(E_2 - E_{2\text{fit}})^2}{\sigma_{E_2}^2},
$$

using the constraint:

$$
\sqrt{2 \cdot E_{1\text{fit}} E_{2\text{fit}} \cdot (1 - \cos \alpha)} = M_{\pi^0},
$$

6
where $\sigma_{E_i}(\text{GeV}) \propto \sqrt{E_i(\text{GeV})}$ are the corresponding energy resolutions of the RCAL.

4.3 Reconstruction of the $\omega$

To determine the invariant mass of the $\pi^+\pi^-\pi^0$ system and the relevant kinematical quantities, the four momentum $p_{3\pi}$ of the $\pi^+\pi^-\pi^0$ system was obtained by adding up the momenta of the two tracks, assuming pion masses, and the momentum of the $\pi^0$. The latter was determined from the measured RHES positions and the fitted RCAL energies $E_{1\text{fit}}$ and $E_{2\text{fit}}$. The quantities $W$ and $p_T$ were then derived from $p_{3\pi}$.

The analysis was restricted to the range $70 < W < 90$ GeV, where the acceptance is almost flat. Furthermore the region $p_T^2 < 0.6$ GeV$^2$ was selected, to limit the background contamination due to proton dissociation.

5 Acceptance calculation and Monte Carlo simulation

The Monte Carlo generators PYTHIA [13] and DIPSI [14] were used to evaluate the acceptance. The former simulates the $\gamma p$ interaction based on VDM and Regge theory, while the $Q^2$ spectrum is generated using the ALLM parametrisation [15] of the $ep$ cross section. The latter uses a model by Ryskin [16], describing vector meson production in terms of a fluctuation of the photon into a $q\bar{q}$ pair, which interacts with the proton via a Pomeron exchange. The effective $W$ dependence of the $\gamma p$ cross section for the events generated was of the type $\sigma \propto W^{0.2}$. Neither model contains initial or final state radiation. The effect of radiative corrections on the cross section has been estimated to be smaller than 4% [3].

The events were generated in the kinematic range $60 \leq W \leq 100$ GeV and $Q_{\text{min}}^2 \leq Q^2 \leq 4$ GeV$^2$. In order to adjust the Monte Carlo calculation to the data, the differential cross section $d\sigma/d|t|$ (see section 7.3) was calculated using the default parameters of PYTHIA and the Monte Carlo events were then re-weighted with the measured slope parameter. The angular distribution of the decay pions was assumed to be that implied by SCHC. The reconstructed $W$, $p_T^2$ and decay angular distributions of the Monte Carlo sample agree well with those of the data, as do the RCAL and RHES energy distributions of the decay photons.

The RCAL trigger efficiency was determined using the data rather than a Monte Carlo simulation. To this purpose a sample of charged pions from the decay of $\rho^0$ mesons produced in elastic photoproduction was used. Since one of the two pions is
sufficient to trigger the event, the efficiency for RCAL to trigger on a charged pion was evaluated as the fraction of events in which the second pion could have satisfied the trigger and in which it actually did. The uncertainty in the resulting RCAL trigger efficiency is limited by statistics and is 6%. The contribution of the photons from the $\pi^0$ decay to the RCAL trigger decision was determined using the Monte Carlo events described above. The total efficiency of the trigger is about 30%. The largest contribution to the inefficiency is the RCAL energy threshold (about 50%).

The acceptance as a function of $W$ and $p_T^2$ is shown in Figure 4. The drop of the acceptance with increasing $W$ or with decreasing $p_T^2$ is due to one or more of the $\omega$ decay products escaping detection in the rear region close to the beam pipe. Conversely, with decreasing $W$ the energy of the photons from the $\pi^0$ decay falls below the value of the cut on the calorimeter energy, thus decreasing the acceptance.

The PYTHIA Monte Carlo sample shows agreement between the reconstructed and generated values of $W$ and $p_T^2$. The relative resolution in $W$ is 6% and the resolution in $p_T^2$ is better than 0.04 GeV$^2$. They are both dominated by the resolution in the energy measurement of the $\pi^0$ decay photons.

A determination of the elastic cross section for $\gamma p \rightarrow \phi p$ using the decay $\phi \rightarrow \pi^+\pi^-\pi^0$ was used as a consistency check (see section 7.2). Also in this case the acceptance was determined using PYTHIA. SCHC was assumed and the events were weighted according to the measured $t$ distribution for this reaction. The average acceptance in the region $70 < W < 90$ GeV is 1.5%.

6 Background

Three sources of background were studied. The first is due to inelastic reactions with dissociation of the photon into a system of large mass. These events produce a smooth mass spectrum, which is parametrised by a polynomial as discussed in section 7.1. A fraction of these events have an $\omega$ in the final state. The efficiency for reconstructing
only the $\omega$ meson is $10^{-5}$. Therefore the contribution of this background to the resonance is negligible.

The main source of background is the inelastic reaction $\gamma p \rightarrow \omega N$, where $N$ is a hadronic system produced by the dissociation of the proton. This background was statistically removed using the results of [3], based on a Monte Carlo simulation with a cross section of the form $d^2\sigma/dtdM_N^2 \propto e^{-|t|}/M_N^3$ ($M_N$ being the mass of the state $N$), with $b = 4.5$ GeV$^{-2}$ and $\beta = 2.5$. In [3] the fraction of elastic $\rho^0$ events was determined as a function of $p_T^2$. A similar determination using the present data was not possible due to statistical limitations. The same fraction of elastic events was therefore assumed here and a $p_T^2$ dependent weight applied to each event to obtain the elastic $\omega$ cross section. The overall effect is to lower the cross section by $16\pm 9\%$. The relative uncertainty on the correction was assumed to be the same as in [3]. The correction was extrapolated to $p_T^2 = 0.6$ GeV$^2$ from the range of the measurement presented in [3].

Contamination from interactions of the proton or positron beam with the residual gas in the beam pipe was estimated from the unpaired bunches to be below 2%.

7 Results

7.1 Analysis of the mass spectrum

The spectrum of the invariant mass of the $\pi^+\pi^-\pi^0$ system $M_{3\pi}$, after all offline cuts and the fit constraining the $\gamma\gamma$ mass according to equation (2), is shown in Figure 3(b). In addition to the $\omega$ signal, a second one is visible, which is due to the elastic photoproduction of the $\phi$ meson, $\gamma p \rightarrow \phi p (\phi \rightarrow \pi^+\pi^-\pi^0)$. The spectrum was fitted with the function:

$$f(M_{3\pi}) = g_1(M_{3\pi}) + g_2(M_{3\pi}) + \zeta(M_{3\pi}),$$

where $g_1$, $g_2$ are convolutions of a non-relativistic Breit-Wigner function with a Gaussian to describe the $\omega$ and $\phi$ resonances. $\zeta$ is a third order polynomial representing the background, mainly due to contamination under the $\pi^0$ peak and to inelastic processes in which a $\pi^0$ is produced. The fitted values of the $\omega$ and $\phi$ masses are $778\pm 3$ MeV and $1020\pm 9$ MeV, respectively, compatible with those of the Particle Data Group (PDG) [17] and with Monte Carlo expectations. The fitted values of the Gaussian standard deviations are $32\pm 4$ MeV and $26\pm 11$ MeV, respectively, also in accord with the Monte Carlo; they are a measure of the resolution of the apparatus.
The number of $\omega$ and $\phi$ candidates observed after background subtraction was determined by integrating the fitted Breit-Wigner functions within the kinematic limits. This yields $N_\omega = 172 \pm 17$ and $N_\phi = 38 \pm 15$.

7.2 Elastic $\gamma p \rightarrow \omega p$ cross section

The elastic $\gamma p \rightarrow \omega p$ cross section is given by:

$$\sigma_{\gamma p \rightarrow \omega p} = \frac{N_\omega}{\epsilon \Phi L B},$$

where $N_\omega$ is the total number of observed events after the statistical subtraction of the inelastic background, $\epsilon$ is the total acceptance, $L$ is the effective integrated luminosity and $\Phi = 0.0203$ is the effective photon flux as given by equation (1) after integration over the selected $W$ and $Q^2$ ranges. The branching ratio of the $\omega \rightarrow \pi^+ \pi^- \pi^0 (\pi^0 \rightarrow \gamma \gamma)$ decay is $B = B_{\omega \rightarrow 3\pi} \cdot B_{\pi^0 \rightarrow \gamma \gamma} = 0.877$ [17]. In the region of $|t| < 0.6$ GeV$^2$, and averaged over the range $70 < W < 90$ GeV, the cross section is:

$$\sigma_{\gamma p \rightarrow \omega p} = 1.21 \pm 0.12(\text{stat.}) \pm 0.23(\text{syst.}) \mu b.$$

The systematic error was obtained by adding in quadrature the individual contributions listed in Table 1; the dominant ones are from the acceptance calculation and the inelastic background subtraction.

The resulting elastic $\gamma p \rightarrow \omega p$ cross section at an average energy of $\langle W \rangle = 80$ GeV is shown in Figure 5 together with previous results from fixed target experiments [18]-[29]. The $W$ dependence of the cross sections in the range $10 < W < 100$ GeV is found to be weak, as predicted by Regge fits to hadronic cross sections [30, 31].

As a consistency check, the elastic $\gamma p \rightarrow \phi p$ cross section was determined, using $B = B_{\phi \rightarrow 3\pi} \cdot B_{\pi^0 \rightarrow \gamma \gamma} = 0.154$ [17] and $\Phi = 0.0207$, resulting in $\sigma_{\gamma p \rightarrow \phi p} = 0.9 \pm 0.3(\text{stat.}) \mu b$. This value agrees with $\sigma_{\gamma p \rightarrow \phi p} = 0.96 \pm 0.19^{+0.21}_{-0.18} \mu b$ determined using the reaction $\gamma p \rightarrow \phi p (\phi \rightarrow K^+ K^-)$ in the kinematic range $60 < W < 80$ GeV and $|t| < 0.5$ GeV$^2$ [5].

7.3 Differential cross section $d\sigma_{\gamma p \rightarrow \omega p}/dt$

In order to derive the differential cross section $d\sigma_{\gamma p \rightarrow \omega p}/dt$, the fit to the mass spectrum described in section 7.1 was repeated in bins of $p_T^2$. To reconstruct the $t$ distribution, a bin-by-bin correction [4], given by the ratio of the generated $t$ and the
reconstructed $p_T^2$ distribution in the PYTHIA Monte Carlo sample, was used to compensate for the difference between $t$ and $p_T^2$, which is a consequence of $Q^2$ not being measured. The result is shown in Figure 6(a). The data were fitted in the range $0 < |t| < 0.6 \text{GeV}^2$ using the functional form:

$$\frac{d\sigma_{\gamma p \rightarrow \omega p}}{d|t|} = A \cdot e^{-b|t|},$$

yielding:

$$A = 10.7 \pm 2.2(\text{stat.}) \pm 2.3(\text{syst.}) \mu b / \text{GeV}^2,$$

$$b = 10.0 \pm 1.2(\text{stat.}) \pm 1.3(\text{syst.}) \text{GeV}^{-2}.$$

The systematic error in $A$ is dominated by the uncertainty on the acceptance (sensitivity to cuts (16%) and model dependence (9%)); the other contributions are the inelastic background subtraction, radiative corrections and luminosity, as listed in Table 1. The dominant contribution to the systematic error in $b$ is also the uncertainty on the acceptance (sensitivity to cuts (12%) and model dependence (4%).

The slope $b$ is compared in Figure 6(b) with the results of previous experiments [19, 20, 22, 24, 25, 28, 29]. From a study of diffractive hadronic processes, assumed to be mediated by Pomeron exchange, Regge theory gives the following dependence of the slope $b$ on $W$ (with $W$ in GeV) [2]:

$$b = b_0 + 2\alpha'_P \ln W^2,$$

with $\alpha'_P = 0.25 \text{GeV}^{-2}$. The line shown in Figure 6(b) represents the dependence according to equation (5), with $b_0$ chosen such that it passes through the ZEUS point. This behaviour is in good agreement with the data points at high energies ($W > 10 \text{GeV}$), where equation (5) is expected to hold.

### 7.4 Decay angular distributions

The polar and azimuthal angles $\theta_h$ and $\phi_h$ of the normal to the $\omega$ meson decay plane in the $s$-channel helicity frame were used to determine elements of the $\omega$ spin-density matrix [32]. The direction of the normal was defined as that of $\pi^+ \times \pi^-$, where $\pi^+$ ($\pi^-$) is the three momentum of the positively (negatively) charged pion. The experimental resolution in $\cos \theta_h$ is about 0.05 and in $\phi_h$ about 0.8 rad. Upon averaging over $\phi_h$ or $\cos \theta_h$ one finds, respectively [32]:

$$\frac{1}{N} \frac{dN}{d\cos \theta_h} = \frac{3}{4} [1 - r_{00}^{04} + (3r_{00}^{04} - 1) \cos^2 \theta_h],$$

11
\[ \frac{1}{N} \frac{dN}{d\phi_h} = \frac{1}{2\pi} \left[ 1 - 2r_{00}^{04} \cos 2\phi_h \right]. \]  

(7)

As the distribution of \( \cos \theta_h \) was found to be symmetric, \( |\cos \theta_h| \) was considered instead. The acceptance corrected distributions of \( |\cos \theta_h| \) and \( \phi_h \) are shown in Figure 7. They were obtained by repeating the mass fits described in section 7.1, applied in each bin of \( |\cos \theta_h| \) and \( \phi_h \). Fits of the functions (6) and (7) to the corrected data yield

\[ r_{00}^{04} = 0.11 \pm 0.08 \text{(stat.)} \pm 0.26 \text{(syst.)} \]

and

\[ r_{1-1}^{04} = -0.04 \pm 0.08 \text{(stat.)} \pm 0.12 \text{(syst.)}. \]

Both values are compatible with the prediction of s-channel helicity conservation: \( r_{00}^{04} = 0.10 \) (assuming a \( Q^2 \) dependence of the ratio of the longitudinal to the transverse \( \gamma^* p \) cross section from VDM as also used in equation (1)) and \( r_{1-1}^{04} = 0 \).

8 Comparison of elastic light vector meson photoproduction measurements

In addition to the measurement presented above, elastic photoproduction of \( \rho^0 \) [3, 4] and \( \phi \) [5] have also been measured at HERA. Table 2 gives a summary of the ZEUS results. The elastic \( \rho^0 \) cross section has also been measured by the H1 collaboration [1], who find a cross section of \( 9.1 \pm 0.9 \pm 2.5 \mu b \) at \( \langle W \rangle = 55 \text{ GeV} \) and \( 13.6 \pm 0.8 \pm 2.4 \mu b \) at \( \langle W \rangle = 187 \text{ GeV} \). We compare in the following our \( \rho^0 \), \( \omega \) and \( \phi \) measurements with each other and with measurements at lower energy, which are presented in Table 3.

From the data of Tables 2 and 3 we calculated the \( \rho^0 \) to \( \omega \) and \( \rho^0 \) to \( \phi \) cross section ratios \( \sigma_{\gamma p \rightarrow \rho^0 p}/\sigma_{\gamma p \rightarrow \omega p} \) and \( \sigma_{\gamma p \rightarrow \rho^0 p}/\sigma_{\gamma p \rightarrow \phi p} \) for \( \langle W \rangle = 12 \) or 14 GeV and 70 or 80 GeV. The results are given in Table 4. If there is the same soft diffractive process mediated by Pomeron exchange for all three vector mesons, no significant energy dependence in these ratios is expected.

Table 4 shows the energy dependence of \( \rho^0 \), \( \omega \) and \( \phi \) elastic photoproduction cross sections, comparing data from this experiment at \( \langle W \rangle = 70 \text{ GeV} \) or \( \langle W \rangle = 80 \text{ GeV} \) with data from fixed target experiments from Table 3.

Using the optical theorem and VDM, the differential cross section \( d\sigma_{\gamma p \rightarrow V p}/d|t| \) for vector meson photoproduction, with \( V = \rho^0 \), \( \omega \) or \( \phi \), can be related to the total vector meson proton cross section \( \sigma_{V p} \), assuming that the real part of the amplitude
is zero:

\[
\frac{d\sigma_{\gamma p \rightarrow V p}}{d|t|} \bigg|_{t=0} = \frac{4\pi\alpha}{f^2_V} \frac{1}{16\pi} \sigma^2_{Vp}, \tag{8}
\]

where \( f^2_V/4\pi \) is the vector meson photon coupling constant. Using equation (8) and the approximate relation:

\[
\frac{d\sigma_{\gamma p \rightarrow V p}}{d|t|} \bigg|_{t=0} = b \cdot \sigma_{\gamma p \rightarrow V p},
\]

one finds:

\[
\sigma_{\gamma p \rightarrow V p} = \frac{4\pi\alpha}{16\pi f^2_V} \frac{1}{b} \sigma^2_{Vp},
\]

At these large energies, the total \( Vp \) cross sections are expected to increase with energy [35] proportionally to \( W^2 \alpha_{IP}(0) - 2 \), where \( \alpha_{IP}(0) \) is the intercept of the Pomeron trajectory. With \( \alpha_{IP}(0) = 1.08 \) [31], and assuming the slope \( b \) to increase with \( W \) according to equation (5), one finds an increase in the elastic vector meson photoproduction cross sections with energy as shown in Table 5. The predictions are consistent with the data. The curve in Figure 5 includes the contribution from Reggeon exchange leading to a smaller predicted increase.

Equation (8) can be used to compute the total \( \omega \) proton cross section. Using \( \frac{d\sigma}{d|t|} \bigg|_{t=0} = 10.7 \, \mu b/ GeV^2 \) (see Table 2) and \( f^2_\omega/4\pi = 23.6 \) [34], one gets

\[
\sigma_{\omega p} = 26.0 \pm 2.5(\text{stat.})^{+3.0}_{-4.2}(\text{syst.}) \, \mu b,
\]

where the systematic error includes the error of \( \frac{d\sigma}{d|t|} \bigg|_{t=0} \) and the estimated uncertainty of \( f^2_\omega/4\pi \). This value agrees with the expected value of 28 mb at \( W = 80 \, \text{GeV} \), obtained from a parametrisation of \( \sigma_{\omega p} = \frac{1}{2}(\sigma_{\pi^+ p} + \sigma_{\pi^- p}) \) [30].

## 9 Conclusions

Elastic \( \omega \) photoproduction at \( \langle W \rangle = 80 \, \text{GeV} \) and \( |t| < 0.6 \, \text{GeV}^2 \) has been measured using the ZEUS detector. The elastic cross section is \( \sigma_{\pi p \rightarrow \omega p} = 1.21 \pm 0.12 \pm 0.23 \, \mu b \). The exponential slope of the differential cross section \( d\sigma_{\gamma p \rightarrow \omega p}/d|t| \) in this \( t \) range has been determined to be \( 10.0 \pm 1.2 \pm 1.3 \, \text{GeV}^{-2} \). The angular distributions of the decay pions are consistent with \( s \)-channel helicity conservation.

When compared to low energy data, the features of \( \omega \) photoproduction as measured at HERA energies are in agreement with those of a soft diffractive process. Previous
measurements of the $\rho^0$ and $\phi$ photoproduction cross sections at HERA show a similar behaviour.

10 Acknowledgement

We thank the DESY Directorate for their strong support and encouragement. The remarkable achievements of the HERA machine group were essential for the successful completion of this work and are gratefully appreciated.

For the design and construction of the RHES special thanks go to D. Cassel, S. Kasai, A. Montag, K.U. Pösnecker, V. Radeka and R. Rau, who contributed in the early stage of the project. The engineering and technical support of the following institutes is gratefully acknowledged: Faculty of Physics and Nuclear Techniques, Cracow; DESY; Univ. of Hamburg; Univ. Autónoma Madrid; Moscow State Univ.; Univ. of Tokyo and Weizmann Institute.

Table 2: Summary of results on elastic light vector meson photoproduction at HERA as measured by ZEUS in the given $t$ range. The values of $\frac{d\sigma}{d|t|}|_{t=0}$ and of $b$ have been taken from a fit of the differential cross section of the form $\frac{d\sigma}{d|t|} = \frac{d\sigma}{d|t|}|_{t=0} \cdot e^{-b|t|}$ in the given $t$ range.
Table 3: Elastic $\gamma p \rightarrow V p$ cross sections from fixed target experiments for $W \geq 9$ GeV. The values listed were obtained as weighted means of the cited measurements.

| $\langle W \rangle$ [GeV] | $\sigma_{\gamma p \rightarrow \rho^0 p}/\sigma_{\gamma p \rightarrow \omega p}$ | $\sigma_{\gamma p \rightarrow \rho^0 p}/\sigma_{\gamma p \rightarrow \phi p}$ |
|--------------------------|-------------------------------------------------|-------------------------------------------------|
| 12 or 14 GeV             | 8.6 ± 1.0                                       | 14.0 ± 1.8                                       |
| 70 or 80 GeV             | 12.2 ± 3.0                                      | 15.3 ± 4.9                                       |

Table 4: Ratios of vector meson photoproduction cross sections.

| $\langle W \rangle$ | $\sigma_{\gamma p \rightarrow \rho^0 p}/\sigma_{\gamma p \rightarrow \omega p}$ | $\sigma_{\gamma p \rightarrow \rho^0 p}/\sigma_{\gamma p \rightarrow \phi p}$ |
|---------------------|-------------------------------------------------|-------------------------------------------------|
| $\langle W \rangle=70$ | $\sigma_{\gamma p \rightarrow \rho^0 p}/\sigma_{\gamma p \rightarrow \omega p}$ | $\sigma_{\gamma p \rightarrow \rho^0 p}/\sigma_{\gamma p \rightarrow \phi p}$ |
| $\langle W \rangle=12$ | $\sigma_{\gamma p \rightarrow \rho^0 p}/\sigma_{\gamma p \rightarrow \omega p}$ | $\sigma_{\gamma p \rightarrow \rho^0 p}/\sigma_{\gamma p \rightarrow \phi p}$ |
| $\langle W \rangle=80$ | $\sigma_{\gamma p \rightarrow \rho^0 p}/\sigma_{\gamma p \rightarrow \omega p}$ | $\sigma_{\gamma p \rightarrow \rho^0 p}/\sigma_{\gamma p \rightarrow \phi p}$ |
| $\langle W \rangle=14$ | $\sigma_{\gamma p \rightarrow \rho^0 p}/\sigma_{\gamma p \rightarrow \omega p}$ | $\sigma_{\gamma p \rightarrow \rho^0 p}/\sigma_{\gamma p \rightarrow \phi p}$ |

Table 5: Ratio of cross sections at high and low $W$. 

Experiment 1.59 ± 0.28 1.12 ± 0.22 1.45 ± 0.46
Pomeron exchange 1.46 1.45 1.28
$b_0$ (from eq. (5)) 6.15 5.75 3.05
Figure 1: Schematic diagram of elastic $\omega$ production in $ep$ interactions.
Figure 2: (a) The area covered by RHES in the RCAL as seen from the interaction point. (b) Extended view of (a), indicating the division of the RCAL EMC into modules and towers. Two RCAL EMC cells fit into one tower. The RHES pads are mounted on support structures, called skis in the figures. (c) Extended view of an RCAL tower. The segmentation of RHES into the pads is shown. $6 \times 3$ pads fit into one RCAL EMC cell.
Figure 3: (a) Invariant mass distribution of the two photons. The full line is the result of the fit explained in the text. (b) Invariant mass distribution of the $\pi^+\pi^-\pi^0$ system after all offline cuts and the fit based on equation (2). The full line is a fit based on equation (3). In both figures the dashed line indicates the background as determined by the fits.
Figure 4: Acceptance for the process $ep \rightarrow e\omega p$. (a) Acceptance as a function of $W$ in the range $|t| < 0.6\text{GeV}^2$. (b) Acceptance as a function of $p_T^2$ in the range $70 < W < 90\text{GeV}$. 
Figure 5: The elastic $\gamma p \rightarrow \omega p$ cross section measured in this experiment (solid circle) compared with the results of fixed target experiments [18]-[29] (open circles). For the ZEUS measurement the inner part of the vertical error bar shows the statistical error, while the outer one shows the statistical and systematic errors added in quadrature. The horizontal bars indicate the $W$ range covered by the measurements. The line is a parametrisation based on Regge fits to hadronic data [30].
Figure 6: (a) The differential cross section $d\sigma_{p\rightarrow\omega p}/d|t|$; the line shows the result of the fit with functional form (4). (b) Exponential slope $b$ of $d\sigma_{p\rightarrow\omega p}/d|t|$ as observed in this experiment (solid circle) compared with low energy data [19, 20, 22, 24, 26, 28, 29] (open circles). For the ZEUS measurements the inner part of the vertical error bar shows the statistical error, while the outer one shows the statistical and systematic errors added in quadrature. The horizontal bars indicate the $W$ range covered by the measurements. The line is given by equation (5). It was constrained to pass through the ZEUS data point.
Figure 7: Acceptance corrected distribution of $|\cos \theta_h|$ and $\phi_h$, where $\theta_h$ and $\phi_h$ are the polar and azimuthal angles of the $\omega$ meson decay plane in the $s$-channel helicity frame, respectively. Fits according to equations (6) and (7) are superimposed.
