ABSTRACT

Hypodontia is the congenital absence of one or more teeth and may affect permanent teeth. Several options are indicated to treat hypodontia, including the maintenance of primary teeth or space redistribution for restorative treatment with partial adhesive bridges, tooth transplantation, and implants. However, a multidisciplinary approach is the most important requirement for the ideal treatment of hypodontia. This paper describes a multidisciplinary treatment plan for congenitally missing permanent mandibular second premolars involving orthodontics, implantology and prosthodontic specialties.

Key words: Hypodontia. Dental implants. Dental prosthesis design.

INTRODUCTION

The congenital absence of teeth can seriously affect a young person, both physically and emotionally, especially when the missing tooth is located in the anterior region of the mouth. Hypodontia is the congenital absence of teeth and refers to the condition where there is an absence of one or a few teeth. In addition, hypodontia of permanent teeth is fairly common in contemporary populations and is the most common human malformation. It occurs without any other signs or symptoms of developmental disorders. Both genetic and environmental components are involved in the etiology of hypodontia, and several genetic and syndromic conditions are currently known to increase the risk of hypodontia; nonetheless, congenitally missing teeth are commonly found in healthy people.

The prevalence of hypodontia ranges from 1% in African Negroes and Australian aborigines to 30% in Japanese people, and studies of white subjects have reported higher frequencies of hypodontia among females (a female-to-male ratio of approximately 3:2). The third molars are the most frequently missing teeth, but they do not need to be replaced; however, mandibular second premolars (2.8%), maxillary lateral incisors (1.6%), and maxillary second premolars and mandibular incisors (0.23%-0.08%) are the most frequently missing teeth that require some type of treatment.

Hypodontia usually requires extensive and complex treatments, ranging from single restorations to surgery and multiple restorations, associated with lifelong maintenance. Several treatment solutions have been presented in the dental literature. In broad terms, the necessary treatment depends on the pattern of tooth absence, the amount of residual spacing, the presence of malocclusion and patient attitudes. One of the key factors for the successful treatment of patients with hypodontia is the interdisciplinary intervention, which involves the close work of a committed team (general dental practitioner, pediatric dentist, orthodontist, implantologist and prosthodontist), where each member contributes with a different expertise to achieve an optimal outcome for the patient. The purpose of this article is to present a case of hypodontia in which the treatment plan consisted...
of the association of orthodontic, implantology, and prosthetic specialties.

CASE REPORT

A 17-year-old male patient in the final stage of orthodontic treatment presented with the primary second molars in position for space maintenance. Hypodontia had been previously diagnosed by the orthodontic team (Figure 1), and the patient was referred to the Oral Rehabilitation Clinic (FOB/USP) for extraction of those teeth and rehabilitation of the area. Analyses of the occlusal condition revealed the presence of both canine and protrusive guidance achieved by orthodontic therapy and that the deciduous second molars were in infraocclusion (Figure 2). The patient did not present with any systemic or genetic disorder that could be associated with hypodontia, and the oral hygiene status was satisfactory.

Several treatment options were considered, including adhesive or conventional fixed bridges and implants, because there were radiographic signs of root resorption in the primary teeth. Considering the consecutive cephalometric analyses, which demonstrated that the patient had reached physical maturity, the bone availability, the absence of medical contraindications, and the patient consent, the treatment comprised the extraction of primary teeth and placement of immediate load implants. However, the mesiodistal dimensions of the primary teeth were larger than that required to restore the anatomy of the mandibular second premolar but insufficient to restore the dimensions of a mandibular first molar. Thus, the only option was to reduce the mesiodistal distance by orthodontic therapy before implant placement. To plan the prosthetic space and at the same time to guide the orthodontic movement, the occlusal surfaces of the primary teeth were marked according to the mesiodistal dimension of a mandibular second premolar (Figure 3), and the distal surfaces were reduced without changing the infraosseous anatomy to acquire space to fabricate the provisional crowns with anatomic characteristics of mandibular second premolars (Figure 4). This step of prosthetic planning was fundamental to the accomplishment of the orthodontic treatment.

After the planned space closure (Figure 5), the teeth were extracted, and external hex implants with a 4.1 mm rectangular platform were immediately placed (Master Porous Grip, Conexão Sistemas de Implante, São Paulo, SP, Brazil) with immediate load (Figures 6). The Ceraone abutment was selected (Conexão Sistemas de Implante) and placed at a torque of 32 N. The provisional crown was then adapted, cemented with temporary cement (RelyX Temp; 3M eSPe, St. Paul, MN, USA) and maintained in infra-occlusion for 4 months. During this period, the orthodontic appliance was maintained for retention of the orthodontically moved mandibular molars. The implants were considered clinically acceptable after clinical (absence of pain, infection, mobility, or any other signal of pathology into the soft tissues) and radiographic (no signs of periimplant radiolucency) examinations.

An impression of the Ceraone abutment was taken with the emergence profile customization technique with silicone (Optosil® and Optosil Xantopren®);

Heraeus Kulzer GmbH & Co. KG, Germany). The metal-ceramic crowns were cemented with glass-ionomer cement (Relay X Luting 2; 3M eSPe). The patient was given maintenance therapy every 6 months during a 2-year period.

The final outcome reflected the care taken, especially during the planning of the prosthetic space to be restored (Figure 7). The 2-year follow-up revealed maintenance of orthodontic treatment,
DISCUSSION

The multidisciplinary approach associated with early diagnosis in individuals with hypodontia of permanent teeth is related to treatment success. However, definitive treatment of the missing teeth is often performed only after eruption of all permanent teeth or completion of orthodontic treatment. The oral patient’s hygiene status and socioeconomic conditions as well as the maintenance therapy should also be considered.

Multidisciplinary treatment is usually initiated upon the diagnosis of hypodontia, often by the pediatric dentist or general practitioner. The main contribution of these professionals is the prevention of carious lesions and maintenance of the primary teeth in the oral cavity for space maintenance and preservation of alveolar bone for future implant therapy. Orthodontic treatment allows for the creation or redistribution of spaces for later rehabilitation. If the primary teeth had not been maintained in the present case, the final prosthetic spaces would not have been large enough for the placement of crowns with the dimensions of mandibular second premolars. The greatest challenge in the treatment of hypodontia is related to treatment planning, which usually depends on the severity of the hypodontia. The treatment options available for these cases are the maintenance of the primary teeth; orthodontic space closure; space maintenance; restoration with adhesive or fixed dentures, tooth transplantation or dental implants; or orthodontic space redistribution to facilitate the prosthetic treatment.

Maintenance of the primary teeth should be considered if root resorption has not affected their stability. When extraction of the primary teeth is indicated, orthodontic treatment should be performed to prevent migration of the adjacent and antagonist teeth and to allow for adequate space for prosthetic rehabilitation. In the present case, besides the maintenance of the primary teeth throughout the orthodontic treatment, the prosthetic spaces preserved by provisional crowns were also important because if they had not been completely closed, the Class I angle could not have been achieved, possibly causing occlusal and facial alterations, while the maintenance of the original space would require prosthetic crowns with different characteristics than those observed on either first molars or second premolars.

The treatment with dental implants may be the best option for patients with hypodontia because this procedure is predictable, stable and provides excellent esthetic results. Other treatment options, such as conventional partial fixed dentures, may cause biological damage due to the need to reduce the intact tooth structure; in young patients, the risk of pulp damage is high due to the large volume of the pulp chamber. When treatment with dental implants is indicated, the possible postpubertal vertical growth of the facial skeleton should be considered, and consecutive cephalometric analyses should be performed to establish the period of growth. These analyses revealed completion of physical growth of our patient; thus, restoration of the prosthetic space with implants was the treatment of choice.

The implant therapy in individuals with hypodontia may be complex due to the limitations caused by the reduced bone thickness, impairing the ideal positioning of implants or requiring the use of implants with a small platform. For this reason, bone grafting is often indicated to compensate for this deficiency. Implants with a small platform prevent the achievement of an adequate emergence profile for wide teeth, such as the posterior teeth. In this case, the maintenance of the primary teeth during orthodontic treatment favors the maintenance of the bone architecture, allowing for the placement of implants with a regular platform.
CONCLUSION

The successful management of hypodontia in this case was achieved by a multidisciplinary treatment. Maintenance of the primary teeth combined with orthodontic treatment allowed for the placement of endosseous implants to replace the missing teeth, enhancing the esthetics and function.
