ABSTRACT
We have carried out $N$-body simulations for rotating star clusters with equal mass and compared the results with Fokker-Planck models. These two different approaches are found to produce fairly similar results, although there are some differences with regard to the detailed aspects. We confirmed the acceleration of the core collapse of a cluster due to an initial non-zero angular momentum and found a similar evolutionary trend in the central density and velocity dispersion in both simulations. The degree of acceleration depends on the initial angular momentum. Angular momentum is being lost from the cluster due to the evaporation of stars with a large angular momentum on a relaxation time scale.

Key words: celestial mechanics, stellar dynamics – globular clusters: general

1 INTRODUCTION
There are two different approaches to study the dynamical evolution of collisional stellar systems (for example, globular clusters): statistical approach and direct integration of the $N$-body equations of motion. Among the statistical methods, the Fokker-Planck (henceforth referred as FP) equation, which is a second order approximation of the collisional Boltzmann equation, has been frequently used. The FP equation is solved by using either Monte Carlo techniques (e.g., the series of eight papers, from Spitzer & Hart 1971 to Spitzer & Mathieu 1980, see also an alternative approach by Hénon 1971, and for recent adaptations Giersz 1998, Joshi, Rasio, & Portegies Zwart 2000, Freitag & Benz 2001), or the direct numerical solution of the discretized FP equation on a mesh. In this paper we focus on the latter approach. One-dimensional (1D) FP models assuming a spherical symmetry and isotropic velocity dispersion have been extensively exploited during the last several decades, and they have successfully elucidated the full dynamical history of star clusters (Cohn 1980; Drukier et al. 1992). Two-dimensional (2D) anisotropic models are a generalization of the 1D model, in which the anisotropy of the velocity dispersion between the radial and the tangential directions is taken into account; however, the isotropized distribution function continues to be used for determining the diffusion coefficients (e.g., Takahashi 1995, 1996, 1997).

The statistical methods have to make several simplifying approximations and have some limitations. More realistic simulations can be performed by directly integrating the complete equations of motion of all stars. However, the $N$-body integration still requires a huge amount of computing power. An improvement in computing facilities, particularly the advent of special purpose hardware such as GRAPE machines (Makino & Tajji 1998; Makino et al. 2003; Fukushige, Makino & Kawai 2005), made it possible to perform a high accuracy $N$-body simulations with one million body (Makino & Funato 2005; Berczik et al. 2006; Iwasawa et al. 2006; Harfst et al. 2006). The comparisons between the results obtained from 1D or 2D FP models and direct $N$-body models gener-
ally show good agreement (e.g., Spurzem & Aarseth 1996). Comparative studies that use the currently available $N$-body solver for studying the dynamical evolution of collisional stellar systems are very important for checking the validity and limitations of the statistical methods. There have been several previous researches involving comparative studies (Giersz & Heggie 1994a,b, 1997; Giersz & Spurzem 1994; Khalisi, Amaro-Seoane & Spurzem 2005; Freitag, Rasio & Baumgardt 2006) and the comparisons show that for isolated non-rotating star clusters the results of FP simulations are generally in good agreement with those of $N$-body simulations. However, when a tidal boundary is included, a discrepancy between the $N$-body and FP models arises; this discrepancy becomes sensitive to $N$ because the relaxation and crossing time scales are related to different dynamical processes (Takahashi & Portegies Zwart 1998, 2000; Baumgardt 2001). For example, the treatment of the tidal boundary has to be performed carefully in FP models since the mass evaporation process involves both orbital dynamics and two-body relaxation. The $N$-body model has to imitate the FP technique to remove stars immediately if they acquire an energy higher than the tidal energy; with these precautions, good agreement can be obtained (Spurzem et al. 2005).

Another extension of the $1D$ FP model was carried out to include the effects of rotation. The first numerical simulation of FP models for rotating clusters was pioneered by Goodman (1983), but neither the results nor the code was published. A more detailed and extended work by Einsel & Spurzem (1999, henceforth referred as Paper I), who developed a new $2D$ FP code named “FOPAX” for this study from scratch, revealed that rotating clusters collapse faster than non-rotating ones. A post core collapse study of rotating star clusters involving comparisons between $N$-body and FP methods (Boily 2000; Boily & Spurzem 2000; Ardi, Mineshige & Spurzem 2006; Ernst et al. 2007). Although these authors found good agreements between these two methods, the number of cases studied is rather limited. This can be understood in two ways. First, for a smaller value of $N$ (say up to a few $10^3$) a large number of statistically independent simulations are needed, and only the ensemble average can be compared with the approximate FP models. On the other hand, different physical models, such as isolated or tidally limited models, different degree of central concentrations of stars (i.e., different central potential), need to be studied. In this paper, we have carried out a series of numerical $N$-body simulations of rotating stellar systems, which are directly comparable with our $2D$ FP models in Papers I and II. By comparing the results with those obtained from FP models, we can investigate the validity of the assumptions made in rotating FP models.

This paper is organized as follows. In the next section, we briefly describe initial $N$-body models and compare them with FP models. In section 3, we present the numerical results obtained from $N$-body simulations and their comparisons with those of FP models. The summary and discussions are given in the last section.

2 THE MODELS

2.1 Numerical methods

The Fokker-Planck (FP) code FOPAX, which takes into account the effect of rotation, was developed in Papers I, II, and III in order to study the secular evolution of star clusters having initial rotation.

For performing direct $N$-body simulations to study the dynamical evolution of rotating stellar systems, we have used the currently available high ac-
have constructed the initial models for the conditions as those of 2D FP models in Paper II. We according to Lupton & Gunn (1987). Our initial models only because the number should be close to the initial angular momentum on cluster dynamics and in comparisons with FP simulations.

2.2 Initial models and boundary condition

In Paper II, the initial 2D FP models are generated according to Lupton & Gunn (1987). Our initial N-body models that follow rotating King models with a central concentration of $W_0 = 6$ have the same conditions as those of 2D FP models in Paper II. We have constructed the initial models for the N-body simulations from the 2D FP models in Paper II by random number generation. Three different initial rotations ($\omega_0 = 0.0, 0.3,$ and $0.6$) are considered in the present work. In Table 1, we list some information on the initial models used for the present simulations.

| $W_0$ | $\omega_0$ | $r_t/r_c$ | $r_h/r_c$ | $T_{tet}/|W|$ | $N$ |
|-------|-------------|-----------|-----------|----------------|-----|
| 0.0   | 18.0        | 0.15      | 0.000     | 10240          |
| 6     | 0.3         | 14.5      | 0.035     | 10240          |
| 0.6   | 9.6         | 0.24      | 0.101     | 10240          |

$a \ T_{tet}/|W| : \text{ratio of rotational energy to potential energy}$

curacy, collisional N-body code NBODY6 (Aarseth 1999). The NBODY6 code uses the fourth-order Hermite scheme with hierarchical block time steps (HTS) and the Ahmad-Cohen neighbor scheme for particle integration. Close encounters between stars and persistent binaries formed by three-body interactions are solved for their internal motion by using two-body regularization methods (Kustaanheimo & Stiefel 1965) and chain regularization (Mikkola & Aarseth 1990, 1993, 1996, 1998). Although NBODY6 is capable of dealing with many more astrophysical components such as the existence of primordial binaries and stellar mass-loss due to stellar evolution, we have considered only the treatment of close encounters between stars in the present study since we are mainly interested in the role of the initial angular momentum on cluster dynamics and in comparisons with FP simulations.

The number of stars ($N$) in a cluster is one of the important parameters for the dynamical evolution of the cluster. While the computational burden (except for the core-collapse phase) does not significantly depend on $N$ in statistical FP method, the number of stars is very important in the N-body simulation as the computation time becomes nearly proportional to $N^3$. We use $N = 10240$ for the present equal-mass models only because the number should be close to that used in Paper II ($N = 5000$). In testing the validity of our FP models, it does not matter that the actual number of stars in globular clusters is significantly larger. The choice of the number of stars determines the relative strength of the three-body interactions, which initiate the post-collapse phase (see e.g., Spurzem & Aarseth 1996).

The realization of the rotating King model for N-body simulations is shown in Figs. 1 and 2. We have shown the radial profiles of density for both the N-body and FP models (Fig. 1) and the distribution of the radial and tangential velocities of the stars in the N-body realization of the rotating King models (Fig. 2). Three N-body models having different degrees of rotation are compared with the 2D FP models. Each density profile is obtained from the mean of 10 different initial models generated by different random seed numbers. The open circles represent the density profile adopted in the FP models. Each $r_{tid,0}$ is the initial tidal radius derived from the FP model. Excellent agreement is observed between the radial profile beyond the core radius ($r_c$) in the N-body realization and that in the FP model. However, within $r_c$, the density of the N-body model is slightly lower than that of FP model. This may be due to the fact that the number of stars inside the core is rather small. However, due to inevitable random fluctuations, it is impossible to construct initial N-body models perfectly identical to the FP models. We believe that statistical FP models agree very well with the averaged N-body
models and increasing the number of stars will improve the degree of agreement. Fig. 1 also shows that increasing the rotation decreases the concentration of the stellar system (smaller ratio between the tidal and the core radii).

The position-velocity distributions that are sky-projected are displayed in Fig. 2 for the N-body models of non-rotating ($\omega_0 = 0.0$, left panels) and highly rotating ($\omega_0 = 0.6$, right panels) clusters with the central potential of $W_0 = 6$. To have maximum effect of initial rotation in sky projected distribution we project the model clusters on sky in such a way that the rotating axis is a perpendicular axis in sky-projected plane. The distance to the rotation axis is measured in units of initial core radius. We also show the mean radial velocity distribution along the projected equator is shown by filled circles with $1\sigma$ errors. The central solid body rotation and the subsequent highly differential rotation are typical of rotating clusters (see Fig. 10 of Paper II for comparison).

3 RESULTS

3.1 Core collapse, central density, and central velocity dispersion

We start the discussions by presenting the results for the evolution of the central density and central velocity dispersion (Fig. 3). The central density increases with time due to the two-body relaxation for an equal-mass system, where the time is measured in units of initial half-mass relaxation time ($\tau_{r,h,0}$). The expression for $\tau_{r,h,0}$ for the equal-mass system is given by the following formula (Spitzer & Hart 1971):

$$\tau_{r,h,0} = 0.138 \frac{N^{1/2} r_{h,0}^{3/2}}{G^{1/2} m^{1/2} \ln \Lambda},$$

where $N$, $r_{h,0}$, $G$, $m$, and $\ln \Lambda = \ln(\gamma N)$ denote the total number of stars, initial half-mass radius, gravitational constant, mean mass of stars and Coulomb logarithm, respectively. It has been shown by Giersz & Spurzem (1994) and Giersz & Heggie (1994a,b) that the best agreement between the direct N-body calculations and orbit-averaged FP equation is achieved when the coefficient $\gamma$ in the Coulomb logarithm has a value of 0.11. Therefore we use this value in the present work as it is also used in Paper II. Since the half-mass radius varies with the rotation parameter.
Comparative study between N-body and Fokker-Planck simulations for rotating star clusters: 1. Equal-mass system

ω₀, the values of τ_rh,0 could also depend on ω₀, even for models with the same W₀.

The time of core collapse (t_{cc}), the time for the complete disruption of the cluster (t_{dis}), and the cluster mass at the time of core collapse in units of initial cluster mass (M_{cc}) are listed in Table 2. We can easily notice that the rotating models evolve faster than the non-rotating ones, in both the N-body and FP models. The faster the cluster rotates the shorter the time taken for the core collapse. As discussed in detail in Papers I & II, the acceleration is caused by the combination of gravothermal and gravogyro instabilities.

In Fig. 3, we show the evolution of the central density (ρ_c) and central velocity dispersion (σ_c) of the cluster. The results obtained from the FP and N-body models are displayed as smooth lines and solid lines with a large fluctuation, respectively. Although the core collapse occurs at slightly different times (one can estimate t_{cc} more accurately in Fig. 4), there is good agreement between the FP and N-body results. The N-body model produces rather noisy data since there is a significant statistical fluctuation in the physical parameters. However, we can still perform some quantitative comparisons between the FP and the N-body approaches. In the early evolutionary stage, the central density derived from the N-body is less than the value obtained by FP for the model with ω₀ = 0.6. This may reflect the difficulty in determination of the central density for N-body models, especially for rapidly rotating clusters that are significantly flattened. Therefore, the most rapidly rotating model has the largest discrepancy with regard to the central density between the N-body and the FP models.

From Table 2, we notice that the times for core collapse in the FP simulations are generally greater than those in the N-body simulations by 5–15%. Apparently, different approaches should yield some different results, and we regard a small difference of 5–15% in t_{cc} as being insignificant. These differences would decrease for large N models as the assumptions made in the FP method become more appropriate. In fact, we have observed that t_{cc} decreases for model with large N value when we compared the simulations performed for N-body models with N = 5000 and N = 10240.

After the core collapse, the evolutions of ρ_c derived from the N-body and FP models are also somewhat different from each other. Toward the end of the evolution, the difference becomes quite significant. The disruption time of the N-body models is slightly larger than that of the FP models. This is due to the fact that the escape rate varies with the number of stars. We perform more detailed comparisons on the evaporation of stars in section 3.3. It is easier to determine the exact core collapse time based on the evolution of the central velocity dispersion because the fluctuation amplitude is smaller than that of the central density. The times of core collapse listed in Table 2 are determined by inspecting the behavior of σ_c.

We show the evolution of the Lagrangian radii of the equal-mass models in Fig. 4. The results from the FP simulation are displayed by the dashed lines. Each line represents the radii where the cluster contains 1%, 5%, 10%, 20%, 50%, and 75% of the initial mass.

|        | 0.6   | 7.27        | 10.08                  | 0.33                   |           |

Figure 5. The evolution of $\sigma_c$ as a function of $\rho_c$. $\sigma_c$ follows power laws during pre- and post-collapse states. The evolution is nearly independent of $\omega_0$.

mass of the cluster. It is not straightforward to determine the Lagrangian radii in a flattened system. In Paper I, the Lagrangian radii were evaluated along the specific zenith angle where the effects of flattening on the mass shells are expected to be less important; the same zenith angle is used in Fig. 4. However, as our models are nearly spherical, we determine the Lagrangian radii on the assumption that the system is spherically symmetric for the N-body models. As seen in Fig. 4, differences between the FP and the N-body models are very small. Analyzing in more depth, we notice that after the core collapse, the inner part of the cluster expands more rapidly in the FP model than in the N-body model, although the difference is rather small.

The relationship between the central density and the central velocity dispersion is shown in Fig. 5. The upper-left panel (Fig. 5a) shows the relation between $\sigma_c$ and $\rho_c$, which is obtained from all the three FP models with different initial rotations. The other three panels (Figs. 5b, 5c, and 5d) show the results of the N-body models. From Papers I and II, we know that this relationship is not affected considerably by the initial rotation, as shown in Fig. 5a. Again, we find good agreement between the FP and the N-body models. The large amount of scatters during the post core collapse phase, as shown in Fig. 5 is mainly due to the large fluctuation in the central density. The power-law behavior of $\sigma_c$ on $\rho_c$ during the pre-collapse phase is a consequence of the self-similarity of the collapsing core and it is well known that $\sigma_c \propto \rho_c^{-1/2}$ during this stage (Cohn 1980). During the post-collapse phase, we can derive the relationship between $\sigma_c$ and $\rho_c$ using an energy balance argument and the assumption of self-similar evolution (see section 3.4). It follows that $\sigma_c \propto \rho_c^{\beta}$ with $\beta = 0.25$, which is in good agreement with $\beta = 0.23$ derived from the FP model in Paper II. The N-body results appear to follow similar power-law behavior, although the power-law index $\beta$ is difficult to determine because of the large scatter.

From the N-body calculations, we have confirmed the earlier finding of a significant acceleration in cluster evolution due to rotation, which was obtained from the FP calculations in Papers I and II. We also find that both the N-body and FP models give similar results, although there are small differences with regard to the time of core collapse, and the disruption times.

3.2 Evolutions of anisotropy and angular momentum

In axially symmetric systems, the natural decomposition of velocity vectors is to use the cylindrical coordinate which has its origin at the center of mass of the cluster. We investigate the evolution of the velocity dispersions ($\sigma_R$, $\sigma_\phi$, and $\sigma_z$) and show the evolution of these quantities in Fig. 6, where $(R, \phi, z)$ represents the conventional axis of the cylindrical coordinate system.

For initially rotating models, these three velocity dispersions have different values. In the right panels of Fig. 6, the ratio of $\sigma_\phi$ to $\sigma_0$ is initially greater than 1 for the rotating models and approaches the isotropic value of 1, where $\sigma_0$ represents the average 1D velocity dispersion defined by $\sigma_0 = (\sigma_R^2 + \sigma_\phi^2 + \sigma_z^2)^{1/2}/\sqrt{3}$.

The angular momentum in rotating stellar systems is transferred outward through two-body relaxation, and is also lost due to escaping stars. The stars gaining a large angular momentum migrate to the outer parts of the system, while those losing angular momentum drift towards the central parts. As the stars with a high angular momentum move outward and finally escape from the cluster, the total angular momentum of the system decreases with time.

In Fig. 7, we display the evolutions of the $z$-component of the angular momentum per unit mass ($J_z$) of an entire cluster. The results from the N-body models are shown by solid lines, while those from the FP models are shown by dashed lines. To indicate the degree of error in determining $J_z$, we also show the
Comparative study between N-body and Fokker-Planck simulations for rotating star clusters: I. Equal-mass system

Figure 6. Time evolutions of $\sigma_R$, $\sigma_\phi$, and $\sigma_Z$ (left panels) and $\sigma_\phi/\sigma_0$ (right panels) for each models. At the time of core collapse, $\sigma_R$, $\sigma_\phi$, and $\sigma_Z$ are almost equal and $\sigma_\phi/\sigma_0$ is $\approx 1$, where $\sigma_0$ is the 1D velocity dispersion.

Figure 7. Evolution of the $z$-component of angular momentum per unit mass ($J_z$) (Fig. 7a) and the loss rate of $J_z$ (Fig. 7b). The results for the N-body model and FP model are shown with solid lines and dashed lines, respectively. The $J_z$ evolution for the non-rotating model indicates the corresponding error in determining the $J_z$. It is clearly shown that $J_z$ for rotating models decreases with time due to the escape of stars possessing an angular momentum. The combined effect of gravitation and rotation accelerates the evolution of the cluster. A substantial loss of the initial angular momentum in an entire cluster prevents rotation from playing an important role in the evolution of a cluster in later phases. Since the cluster is losing mass at a nearly constant rate, the total angular momentum of the cluster decreases more rapidly than $J_z$.

Figure 8. Distribution of the $V_\phi$ at 4 selected evolutionary epochs in cylindrical coordinate system for a model with $(W_0, \omega_0) = (6, 0.6)$. When there is no rotation, it should show a symmetry with respect to $V_\phi = 0$. A asymmetry of $V_\phi$ disappears with increasing time due to the loss of the angular momentum. The filled circles are the average $V_\phi$ values and the error bar corresponds to 1 $\sigma$ dispersion.

3.3 Evolutions of rotation curve

We can construct the rotation curves by computing the averages of $V_\phi$, which is the $\phi$-component of the velocity of stars. We choose the model with $\omega_0 = 0.6$ and present the distribution of $V_\phi$ for all stars at some specific epochs in Fig. 8. The asymmetry of $V_\phi$ with respect to $V_\phi = 0$ indicates the global rotation of the stellar system. During the pre-collapse phase, $V_\phi$ becomes more dispersive, particularly around the central region. A large spread near the center ($R \sim 0$) at

**Figure 10.** Density distribution of stars in \((R, Z)\) coordinate at four selected evolutionary epochs for a model with \((W_0, \omega_0) = (6, 0.6)\) as computed by N-body (contour map) and FP methods (color map). The horizontal axis is \(R\) running from 0 to 3 in units of the initial core radius, while the vertical axis is the \(z\) coordinate with the same scale. The N-body and FP methods give almost the same density distribution.

3.4 Tidal boundary

If the cluster rotates around the host galaxy on a circular orbit, the tidal field experienced by the cluster...
Comparative study between $N$-body and Fokker-Planck simulations for rotating star clusters: I. Equal-mass system

Figure 11. The evolution of the total mass of the cluster. The discrepancy between FOPAX and NBODY6 is mainly due to the number of particles after the core collapse.

The tidal radius is expressed as follows:

$$r_{\text{tid}} \approx \left( \frac{M}{3M_G} \right)^{1/3} R_G,$$

(3)

where $M$ is the total mass of the cluster within the tidal boundary; $R_G$, the distance of the cluster from the galactic center; and $M_G$, the galactic mass within $R_G$. The above equation ensures that the mean density within the tidal radius is a constant. As the cluster loses the stars beyond the tidal boundary, the tidal radius has been adjusted to maintain a constant mean density.

We depict the evolution of the total mass of the cluster in Fig. 11. During the pre-collapse phase, the evolution of the total mass, which is computed from the $N$-body and FP models, are similar but shows small deviation each other. However, after the core collapse, the two methods result in somewhat different behavior. This discrepancy in the post-collapse phase is partly due to the accumulation of small difference during the pre-collapse phase. The escape rate of the $N$-body simulation is lower than that of the FP simulation. This may be caused due to the decrease in the number of stars in the cluster. We have assumed the instantaneous escape of stars whose energy exceeds the tidal energy. Therefore, $t_{\text{cross}}/t_{\text{relax}}$ increases as $N$ decreases. This means that the $N$-body simulation removes stars less effectively than the FP simulation for small value of $N$; this is why we observe a long tail in the $N$-body results in Fig. 11. In $N$-body simulations, after the core collapse, the number of stars remaining in the cluster is of the order of $10^9$. This is not a sufficient number to obtain results comparable with the FP method. Hence, the escape rate for $N$-body models is lesser than that for the FP models during the late stages of the evolution and $N$-body models survive longer than FP models. We can also observe this effect in Fig. 3.

In this figure, central density features are observed to be inconsistent between the $N$-body and the FP models toward the end of the evolution. With more stars, this gap would become narrower. Since the number of stars in a real globular cluster is considerably larger than that used in the present $N$-body simulations, the difference between $N$-body and FP models would decrease for a realistic number of stars (see Takahashi & Portegies-Zwart 1998).

3.5 Core, half-mass, and tidal radii

We now investigate the evolution of the core, half-mass, and tidal radii of the star cluster. The behavior of $r_{\text{tid}}$ and $r_c$ in units of initial half-mass radius ($r_{h,0}$) is shown in Fig. 12. As the rapidly rotating initial model has a half-mass radius smaller than the slowly rotating model, the initial value of $r_c/r_h$ for the most...
rapidly rotating cluster is larger than that of the other two models, as shown in Fig. 13 (Paper II). The evolutions of \( r_c \) and \( r_{tid} \) in units of \( r_h \) at the same evolutionary stage as those in Fig. 12 are shown in Fig. 13. We find that there are significant differences in \( r_c/r_h \) between the FP and the N-body models, while the difference is not so apparent in \( r_{tid}/r_h \). This reflects the difficulties in determining \( r_c \) for the N-body models with a relatively small value of \( N \) rather than any systematic differences in different approaches. Both \( r_c \) and \( r_h \) decrease with time, although there is a difference in the decreasing rate that depends on the initial degree of rotation. After the core collapse, both \( r_c \) and \( r_h \) increase for some time at almost the same rate due to self-similar expansion. Subsequently, the tidal boundary shrinks rapidly after core bounce. Therefore, the half-mass radius begins to decrease again. However, the shrinking of \( r_{tid} \) does not affect the central region and \( r_c \) continues to increase. At the end of the evolution, \( r_c \) shows a steep increase; this signals the complete disruption of the cluster.

After the core collapse, \( r_c/r_h \) and \( r_{tid}/r_h \) show nearly the same behavior. The value of \( r_c/r_h \) is almost constant and the evolution of \( r_{tid}/r_h \) for different initial models is similar to each other and independent of the rotation parameter \( \omega_0 \). We already have assumed the self-similar evolution of the inner part of the stellar system in order to explain the relation between \( r_c \) and \( \sigma_c \) after \( t_{cc} \) (Fig. 4). We can express \( \sigma_c^2 \sim \frac{M_c}{r_c} \) and \( \sigma_h^2 \sim \frac{M_h}{r_h} \), where \( M_c \) and \( M_h \) are the masses within \( r_c \) and \( r_h \), respectively. Since the inner parts of the cluster are nearly isothermal, we obtain \( \sigma_h/\sigma_c = constant \). With the self-similarity assumption \( (r_c/r_h = constant) \), we can rewrite \( \sigma_c \) as \( \sigma_c \sim \rho_h^{1/6}M^{1/3} \). On the other hand, according to Goodman (1987), the energy balance argument predicts that \( \rho_c/\rho_h \propto M^{4/3} \). Therefore, \( \sigma_c \sim \rho_c^{1/4}r_h^{-1/12} \). If we use the tidal boundary condition, \( M/r_{tid} = constant \) and \( \rho_h \sim \frac{M}{r_h} \), we can obtain the following relation:

\[
\ln \sigma_c \sim \frac{1}{4} \ln \rho_c - \frac{1}{4} \ln \frac{r_{tid}}{r_h}.
\]

(5)

The variation in \( \frac{\sigma_{tid}}{\rho_h} \) during the post-collapse phase is very small (by a factor of few) as compared with that in \( \rho_c \) (by a few orders of magnitude), except near the disruption time. Therefore, we can approximately write following relation:

\[
\ln \sigma_c \sim \frac{1}{4} \ln \rho_c.
\]

(6)

If we express \( \sigma_c \propto \rho_c^\beta \), \( \beta = 0.25 \), then. This value is close to 0.23 that was achieved in Paper II.

4 SUMMARY AND DISCUSSION

We have performed numerical simulations for the evolution of initially rotating star clusters with equal mass using NBODY6 and have compared the results with those computed by the direct integration of the Fokker-Planck equation. We have considered clusters with \( N = 10240 \). For critical comparisons between N-body and FP models, we constructed the initial N-body models using the initial 2D distribution function used for FP models.

We observed the acceleration of the core collapse, as reported in Papers I & II. The degree of acceleration obtained from the present N-body models is slightly different from that obtained from the FP models; however, the small difference in the core-collapse time between the N-body and statistical methods (FP model, gaseous model, etc.) has also been observed earlier (Spurzem & Aarseth 1996). The entire evolutionary trend of the central density agrees with that of the FP models.

The \( z \)-component of the specific angular momentum \( (J_z) \) is observed to monotonically decrease with time for the clusters with initial rotation. The global evolutionary trend of \( J_z \) between the N-body and the FP models shows excellent agreement. The loss rate of \( J_z \) decreases as the cluster evolves. Therefore, we conclude that during the early stages the existence of initial rotation significantly affects the entire cluster evolution.

In FP simulations, the cluster evolution will be independent of the third integral to the end of time. On the other hand, in the N-body simulations, the third integral effect may appear during the evolution. In addition, there is a limit on the number of stars and the random fluctuations of the N-body models in this study and these limits also cause differences with the FP method. Therefore, we need to perform more N-
Comparative study between N-body and Fokker-Planck simulations for rotating star clusters: I. Equal-mass system

body simulations with a larger number of stars or with various models by using different random number.
