ABSTRACT

A study was conducted to examine the clinical signs, hematological, biochemical and histopathological changes in vitamin D₃ toxicity at a dose rate 2 mg/kg b.wt. of vitamin D₃ and to assess the protective effect of Aloe vera in vitamin D₃ toxicity. The clinical signs observed were anorexia, progressive weight loss, difficulty in movement and respiration, diarrhea, epistaxis, subnormal body temperature and nervous signs before death. Mortality was observed in treated rats between day 10 and day 19 of treatment. The gross postmortem changes observed were severe emaciation, white chalky deposits on epicardial surface of heart, pin point white deposits on cortical surface of kidneys with pale yellow discoloration and diffused white deposits on serosal surface of stomach and intestine with bloody ingesta in lumen. The hematological changes included non-significant increase in hemoglobin and total leukocyte count and significant increase in relative neutrophil count. The biochemical changes observed were significant increase in plasma concentration of calcium, phosphorus and blood urea nitrogen, whereas a significant decrease in the concentration of albumin and total plasma protein was observed. The histopathological lesions included calcification of various organs, viz., tongue, stomach, intestines, kidney, heart, aorta, larynx, trachea, lungs, spleen, choroid plexus arteries of brain and vas deferens. The Aloe vera juice (2.5% in drinking water) has no protective effect on vitamin D₃ toxicity (2 mg/kg b.wt.).

Key words: Aloe vera, calcification, histopathological lesions, hypercalcemia, vitamin D₃ toxicity

INTRODUCTION

Nowadays, use of vitamin D₃ (cholecalciferol) in commercial pet, livestock and infant feed supplements, multivitamin preparations and as a rodenticide has increased the risk of its toxicity. Various plant species that have a high concentration of vitamin D analogue have been reported as a source of vitamin D₃ toxicity in livestock. The most common source of vitamin D₃ toxicity in dogs and cats is accidental ingestion of rodenticide baits containing cholecalciferol.[1] So, the present study was designed to examine the clinical signs, hematological, biochemical and histopathological aspects and ameliorative effect of Aloe vera on vitamin D₃ toxicity in rats.

MATERIALS AND METHODS

Thirty-two healthy adult male Wistar albino rats were weighed and housed in laboratory animal cages. The rats were fed on standard laboratory animal feed for rat and mice, supplied by Godrej Agrovet Limited, Mumbai. The rats were kept for 7 days to acclimatize in laboratory condition prior to start of sampling protocols. On day 7,
the rats were randomly divided into four groups (A, B, C and D) of eight rats in each group. Group A was given vitamin D₃ orally at 2 mg/kg single dose daily, dissolved in groundnut oil. Group B was given vitamin D₃ orally at 2 mg/kg dissolved in groundnut oil single dose daily and 2.5% commercial Aloe vera preparation in drinking water daily. Group C served as control group and was administered groundnut oil only. Group D was given 2.5% commercial Aloe vera preparation in drinking water daily. The rats were anesthetized by using diethyl-ether inhalation anesthesia method and blood samples were collected by retro-orbital plexus method on day 0, day 10 or just before death in 1% heparin solution for biochemical and in ethylenediaminetetraacetic acid (EDTA) for hematological analysis. Necropsy was performed on rats died due to toxicity and relevant tissues were collected in 10% buffered formalin saline for histopathological studies. The experiment was approved by Institutional Animal Ethics Committee (IAEC), GADVASU, Ludhiana.

**Estimation of biochemical parameters**

The collected blood samples were centrifuged immediately at 1500 rpm for 15 minutes and plasma was separated and stored at 4°C. These plasma samples were used for estimation of biochemical parameters. The biochemical parameters were estimated on auto analyzer by using diagnostic reagent kits (Autopak) supplied by Bayer Diagnostics India Limited, Baroda, Gujarat, India. The mean values of concentrations estimated in plasma of respective groups were compared by using one-way analysis of variance (ANOVA) test.

**Collection, processing and staining of tissue samples for histopathology**

Necropsy of rats that died due to toxicity was performed as early as possible and the tissue/specimens consisting of pieces of various organs were collected in 10% formalin for histopathological examination. The control group rats were anesthetized by using diethyl-ether inhalation anesthesia method and killed by exsanguinations. The formalin-fixed tissues were washed overnight in running tap water, dehydrated in ascending grades of alcohol and cleared in benzene. The 4–5 µm thick tissue sections were cut from the paraffin embedded tissues and were stained with hematoxylin and eosin stain (H and E) for routine histopathology. Wherever necessary, duplicate sections were stained to confirm calcification in tissues with Von Kossa stain.\[2\]

**RESULTS AND DISCUSSION**

**Clinical signs observed**

On day 8 of treatment, the rats of group A and group B were dull and showed decrease in feed and water intake. These signs became more intense with course of treatment. On days 10, 11 and onward, some rats of the treatment groups stopped taking feed and water. They were dull, showing difficulty in movement and rigidity of limbs. They showed ataxic movements or could not even open their mouth. The body coat was ruffled and the animals showed severe cachexia. Diarrhea was observed in rats of groups A and B besides difficulty in respiration, shivering and epistaxis. Before death, there were nervous signs like aimless running, rolling and epileptic seizures. On day 10, one rat from group A and two rats from group B were found dead. Mortality of rats in groups A and B was observed between day 10 and day 19 of treatment.

A significant decrease in body temperature of groups A and B was recorded on day 10 of treatment as compared to their average body temperature before treatment on day 0, while no significant change was found in the body temperature of rats in groups C and D [Table 1].

A significant decrease in body weight of rats in groups A and B was observed on day 10 of treatment as compared to their average body weights before treatment (day 0). The total decrease in average body weight was 23.17% (76.67 g) and 22.61% (80.84 g) in groups A and B, respectively. No significant change was recorded in body weights of groups C and D [Table 2].

The clinical signs of vitamin D₁ toxicity like anorexia, diarrhea, progressive emaciation/weight loss, dehydration,
weakness and difficulty in movement observed in the present study are in consonance with earlier findings in different species. [3,4] Morrow[5] reported that with unregulated increase in plasma calcium and phosphorus in vitamin D₃ toxicity, their product (calcium × phosphorus) can rise above 60, which causes mineralization of tissues/ organs like kidneys, gastrointestinal tract (GIT), cardiac muscles and blood vessels, leading to structural damage with eventual decreased functional capacity. This loss of function contributes to the development of ongoing and end-stage clinical signs as well as long-term signs in animals that survive. In the present study, hypercalcemia and hyperphosphatemia along with mineralization of various organs was observed. Thus, the clinical signs observed were the sequelae of biochemical and histopathological changes due to vitamin D₃ toxicity.

Biochemical findings

The plasma concentrations of various biochemical parameters before treatment and on day 10 of treatment are shown in Tables 3 and 4, respectively. On day 10 of treatment, the plasma concentration of calcium, phosphorus and blood urea nitrogen (BUN) in vitamin D₃ treated groups (A and B) was found to be significantly increased, while the plasma concentration of total plasma protein and albumin was found to be significantly decreased before death as compared to their average values in control groups [Tables 3 and 4].

The increase in calcium levels or hypercalcemia in cholecalciferol toxicity in the present study is in consonance with the earlier studies on vitamin D₃ toxicity by different workers. In vitamin D₃ toxicity, the active metabolites of cholecalciferol have been reported to increase the blood calcium (hypercalcemia) level by increased resorption/mobilization of calcium from bone, increased absorption of calcium from intestine and decreased calcium excretion by kidney. The net result is high concentration of blood calcium level (hypercalcemia) and death reported due to renal and cardiac failure. [6] The significant increase found in the plasma phosphorus levels in the present study is in accordance with findings of earlier studies on vitamin D₃ toxicity. Morrow[5] reported that in case of acute toxicity of cholecalciferol, there is a moderate rise in serum/plasma phosphorus concentration up to 11 mg/dl and it is due to stimulation of transfer of phosphorus along with calcium from bone to plasma. The net result is mineralization of the kidney, GIT, cardiac muscles and blood vessels, causing structural damage and decrease in functional capacity of these tissues and organs. The elevated level of BUN in this study indicates renal damage. Histopathologically, hypercalcemia-induced extensive glomerular and renal tubular damage (nephrocalcinosis) was seen in the present study as reported earlier in vitamin D₃ toxicity. [7] The significant decrease found in the levels of albumin and total plasma protein was thought to be due to loss of protein due to extensive renal damage.
Hematological findings
On day 10, the concentration of hemoglobin and total leukocyte count of groups A and B increased non-significantly as compared to group C (control) rats. The mean relative neutrophil counts of groups A and B increased significantly from group C (control) rats on day 10, whereas counts of other cells differed non-significantly from control rats. The hemoglobin, total leukocyte count and differential leukocyte count of group D rats differed non-significantly from control rats on day 10. The relative increase in neutrophil count could be due to ongoing tissue necrosis as confirmed by histopathological observations.

Gross postmortem changes observed
The rats died due to vitamin D$_3$ toxicity (groups A and B) or sacrificed showing signs of vitamin D$_3$ toxicity had severe emaciation and ruffled body coat. The heart was felt hard with white chalky deposits on epicardial surface. The stomach and intestines showed diffused white chalky deposits on serosal surface. The stomach and intestines revealed bloody ingesta in the lumen with marked hemorrhages on mucosa. Pin point white chalky deposits were observed on capsules of both kidneys [Figure 1]. The liver, lung and other organs grossly appeared normal. Gross pathological changes like bloody ingesta in stomach and intestine were observed in the present study as also reported by Long, [8] due to vitamin D$_3$ toxicity in pigs.

Histopathological findings
The following histopathological changes were observed in the tissues collected from rats died due to vitamin D$_3$ toxicity (groups A and B) or sacrificed rats showing clinical signs of toxicity. The histopathological changes are presented below according to severity of lesions:

Tongue
The lamina propria, connective tissue in-between muscle fibers and tunica intima of blood vessels of tongue showed purple deposits of calcification. Around the calcified areas, there was mild lymphomononuclear cell infiltration. The calcification was also confirmed by Von Kossa staining as black deposits of calcification [Figures 2 and 3].

Stomach
Calcification was observed in mucosa, muscularis mucosa and muscularis externa layers of stomach. Calcification of submucosal and serosal blood vessels was observed. Around the area of calcification, there was lymphomononuclear cell infiltration. Hemorrhagic gastritis was also observed in some rats. The calcification was confirmed by Von Kossa staining [Figures 4-6].

Small and large intestine
The lesions observed in small intestine included calcification of the Brunner’s gland epithelium and sloughing of intestinal villi epithelium. The histopathological lesions in large intestine included calcification of muscularis externa layer [Figure 7].

Kidney
Mineralization (nephrocalcinosis) was observed mainly in cortex and medulla. The tubular epithelium showed calcification and coagulative necrosis along with presence of proteinaceous casts in the lumen. The calcification was also observed in basement membranes of tubules. In medulla, mineralization and degeneration was mainly observed in the collecting tubules. The walls of renal blood vessels showed calcification. Mineralization was observed in glomerular capsules and inside the glomerulus. The deposits of mineralization were also present in interstitium [Figures 8 and 9].

Larynx and trachea
Calcification was observed in lamina propria of larynx. The tracheal cartilage and basement membrane of tracheal mucosal epithelium showed mineralization. The tracheal mucosa was infiltrated with inflammatory cells with exfoliated mucosal epithelial cells [Figure 10].

Lungs
Calcification of bronchial mucosal epithelium was observed. In lungs, brown dirty color granular deposits of calcium were observed in alveolar and interalveolar septae. There was infiltration of lymphocytes, macrophages, occasional neutrophils and few giant cells in the thickened alveolar septae. Other histopathological changes in lungs included marked hemorrhage, emphysema, and edema. The calcification in bronchi and lung was confirmed by Von Kossa staining. The Von Kossa staining of lung sections showed extensive mineralization of alveolar septae [Figure 11].

Heart
Calcification was observed in epicardium, myocardium and endocardium, cardiac valves and coronary arteries. The histopathological changes included calcification, degeneration and replacement of cardiac muscle cells with fibrous tissue along with lymphomononuclear cell infiltration. The epicardium and myocardium were severely affected with extensive fibrous tissue proliferation and severe lymphomononuclear infiltration [Figures 12 and 13].

Aorta
The histopathological changes observed in aorta included calcification and structural derangement of tunica media. The deposits of calcium were observed in between the elastic fibers of tunica media. The elastic fibers of tunica media were widely separated due to calcium deposits in between...

them causing structural derangement. The calcification in aortic media was confirmed by Von Kossa staining [Figures 14 and 15].

**Spleen**
The histopathological changes found in spleen included calcification of central arteries of lymphatic nodules and calcification of capsular surface of spleen [Figure 16].

**Liver**
The histopathological changes observed in liver included fatty/vacuolative degeneration of hepatocytes.

**Adrenal**
There was vacuolation of adrenal cortical cells and marked congestion of medulla.

**Brain**
Calcification of choroid plexus arteries was observed along with other histopathological changes like neuronophagia and satellitosis in cerebral cortex [Figure 17]. The findings are in consonance with earlier findings reported by Morita et al (1995) and Hilbe et al (2000) in cholecalciferol toxicity. Morita et al (1995) and Hilbe et al (2000) reported the calcification of choroid plexus blood vessels in cats and dog respectively.

**Vas deferens**
The histopathological changes observed in vas deferens included the calcification and degeneration of muscle fibers of tunica muscularis layer [Figure 18].

The effects of hypercalcemia on cells include altered cell membrane permeability, altered calcium pump activity, decreased cellular energy production and cellular necrosis. As the toxicity increases, clinical signs including hypertension, polyuria and extremely elevated serum calcium level may cause cardiac arrhythmias.\(^5\)

The mechanism of mineralization or calcification in vitamin D\(_3\) toxicity is well explained by Morrow,\(^5\) who reported that with unregulated increase in plasma calcium and phosphorus in vitamin D\(_3\) toxicity, their product (calcium \(\times\) phosphorus) can rise above 60, which causes mineralization of tissues/organs like kidneys, GIT, cardiac muscles, blood vessels and causes structural damage that leads to decreased functional capacity of these tissues and organs. The loss of function contributes to the development of ongoing end-stage clinical signs as well as long-term signs in animals that survive. The cause of death reported in vitamin D\(_3\) toxicity includes cardiac and renal failure. The histopathological changes observed within various organs in present study are in agreement with earlier reports\(^6-8\) on vitamin D\(_3\) toxicity in different animal species.

Effect of Aloe vera on vitamin D₃ toxicosis

The biochemical, hematological and histopathological parameters of group B (vitamin D₃ at 2 mg/kg dissolved in groundnut oil daily single dose plus 2.5% Aloe vera juice in drinking water daily) were evaluated to assess the protective role of Aloe vera on vitamin D₃ toxicity. These parameters showed same clinical signs, gross postmortem, biochemical, hematological and histopathological changes as observed in group A (vitamin D₃ at 2 mg/kg dissolved in groundnut oil single dose daily), in comparison with control rats. The biochemical and hematological changes in group B (on day 10) differed non-significantly from group A rats.

Kawashima et al.,[10] reported the inhibitory effect of aspirin on vitamin D₃-induced hypercalcemia. Heggers et al.,[11] reported that Aloe vera gel has anti-inflammatory properties like aspirin. The earlier studies also reported the protective effect of Aloe vera in toxicants like lindane and arsenic.[12,13]

In the present study, no protective effect of Aloe vera was found in vitamin D₃ toxicity.

In conclusion, the study revealed clinical signs of severe progressive emaciation, diarrhea, difficulty in respiration and movement, nervous signs like aimless running, rolling and epileptic seizures and subnormal body temperature before death in vitamin D₃ toxicity. The biochemical findings included increased levels of blood calcium, phosphorus and BUN, while a significant decrease was observed in the levels of total protein and albumin. The histopathological findings included calcification of various organs throughout the body. Aloe vera was found having no ameliorative effect against vitamin D₃ toxicity.
