Direct observation of the surface-enhanced Raman scattering (SERS) of molecules adsorbed on nano-sized zirconia (ZrO₂) substrates was first reported without the need for the addition of metal particles. It was found that ZrO₂ nanoparticles can exhibit unprecedented Raman signal enhancements on the order of 10³ for the probe molecule 4-mercaptobenzoic acid (4-MBA). The dramatic effect of the calcination temperature on the ZrO₂ nanoparticles was also investigated. The ZrO₂ nanoparticles with the particle diameter of 10.5 nm, which were prepared by calcination at a temperature of 500°C, have the highest SERS activity. A comparison between the experimental and calculation results indicates that charge transfer (CT) effects dominate the surface enhancement. The plentiful surface state of ZrO₂ active substrate that is beneficial to CT resonance occurs between molecules and ZrO₂ to produce a SERS effect. The CT process depends, to a large extent, on the intrinsic properties of the modifying molecules and the surface properties of the ZrO₂. This is a new SERS phenomenon for ZrO₂ that will expand the application of ZrO₂ to microanalysis and is beneficial for studying the basic properties of both ZrO₂ and SERS.

Keywords: raman, SERS, ZrO₂, charge-transfer, nanoparticle

INTRODUCTION

The large surface-enhanced Raman scattering (SERS) enhancement observed in metals and semiconductors is explained by the vibrational coupling of various resonances in the molecules of the semiconductor system, such as surface plasmons, excitons, charge transfer (CT), and molecular resonance (Yin et al., 2010; Li et al., 2011; Wang and Chen, 2011; Jiang et al., 2013; Wang et al., 2013, 2014, 2016; Huang et al., 2014; Kadkhodazadeh et al., 2014; Mogensen and Kneipp, 2014; Shiohara et al., 2014; Zhao et al., 2014; Shen et al., 2015; Scott and Carron, 2016; Fu et al., 2019). Because semiconductor materials are widely used in the rapidly developing energy and optoelectronic fields, it is important to investigate the SERS mechanism for semiconductor substrates (Lombardi and Birke, 2014; Alessandri and Lombardi, 2016; Han et al., 2017). Semiconductors that can be used as SERS substrates have been identified, such as TiO₂, ZnO, and CdS. These can amplify the Raman signals of surface-adsorbed organic molecules such as 4-mercaptopyridine (4-MPY) and 4-mercaptobenzoic acid (4-MBA) by more than 100-fold (Sun et al., 2007; Wang et al., 2007; Yang et al., 2008).

Nanoparticles of zirconium dioxide ($\text{ZrO}_2$) are one of the most important materials for the preparation of nano-ceramics, and it can prepare ceramic components with various functions (Li et al., 2017). It has applications and developments in solid oxide fuel cells, thermal barrier coating materials, catalyst carriers, lubricant additives, medical, gas sensitive, and wear resistant materials (Duan et al., 2017; Gan et al., 2017; Long et al., 2017; Xu et al., 2017; Wang et al., 2019). The brittleness of ceramic materials limits its practical application, and nanoceramics are a strategic way to solve the brittleness of ceramics. However, grain size is the most important factor affecting the performance of nanoceramics. The decrease of grain size will significantly improve the mechanical properties of materials (Zhang L. et al., 2015). The grain refinement will contribute to the slip between the grains, giving the material plastic behavior. A large number of studies by researchers have shown that the temperature is closely related to the size of $\text{ZrO}_2$ particles, and the transition temperature of $\text{ZrO}_2$ particles below 100 nm can be greatly reduced (Becker et al., 2008). Toughening of ceramics by microcracks and residual stresses generated the conversion of $\text{ZrO}_2$ from a tetragonal phase ($t$-$\text{ZrO}_2$) to a monoclinic phase ($m$-$\text{ZrO}_2$). Therefore, the nano-sized $\text{ZrO}_2$ can significantly increase the strength and stress intensity factor of the ceramic, thereby increasing the toughness of the ceramic (De Aza et al., 2002). Nowadays, the application research on nano-sized ZrO$_2$ has become one of the research hotspots of nano-ceramic new technology. As a new type of high-performance ceramics, the use of highly sensitive SERS technology with in-situ characterization advantages to study the size effect of nano-sized $\text{ZrO}_2$ is expected to promote the better performance of nano-ceramic materials to enable the emergence of new properties and functions.

In addition, $\text{ZrO}_2$ is a particularly attractive candidate to promote CT enhancement because it has recently been shown that the luminescence effect of $\text{ZrO}_2$ materials is derived from transitions between new and ground state energy levels formed by oxygen vacancies that capture electrons and oxygen vacancies produced by the formed association center (Kralik et al., 1998; Chang and Doong, 2007). Owing to the photoelectric properties of $\text{ZrO}_2$, a CT state is readily formed. Currently, there are no reports on the use of $\text{ZrO}_2$ enhancement to obtain SERS (Figure 1).

**MATERIALS AND METHODS**

**Chemicals**

Zirconium nitrate pentahydrate was obtained from Tianjin Guangfu Fine Chemical Research Institute; triethylamine was obtained from XiLong Chemical Co., Ltd.; CTAB were obtained from China Huishi Biochemical Reagent Co., Ltd. 4-Mercaptobenzoic acid (4-MBA), 4-Mercaptopyridine (4-Mpy), and P-aminothiophenol (PATP) were purchased from Sigma-Aldrich. The other chemicals are analytically pure without further purification.

**Synthesis of $\text{ZrO}_2$ Nanoparticles**

The synthesis of $\text{ZrO}_2$ was followed the procedure below (Zhou et al., 2006). First, at room temperature and in a 500 mL round-bottomed flask, mix and dissolve 17.44 g Zirconium Nitrate and 2.95 g Hexadecyl trimethyl ammonium Bromide in 180 mL deionized water. The hydrolysis was carried out with slight stirring. Stirring was continued for about 20 min until a clear sol was obtained. 22.615 mL Triethylamine was added in the solution under rough stirring. The mixture was kept at 75°C for 8 h in the round-bottomed flask. The sol-gel production was dried at 82°C for 48 h. This was the last step after drying the product, eluted with ethanol for 48 h in a Soxhlet extraction. The product was calcined in a muffle furnace for 2 h to obtain $\text{ZrO}_2$ nanoparticles at different temperatures (450–650°C).

**Adsorption of Probing Molecules**

The surface modification of $\text{ZrO}_2$ nanocrystals is obtained as follows: 10 mL 4-MBA ethanol solution concentration $1 \times 10^{-3}$ M was used to dissolve 20 mg of $\text{ZrO}_2$ nanocrystals. The mixture was stirred at room temperature for 4 h and then centrifuged. The 4-MBA molecules that did not adsorb were subsequently removed by rinsing the precipitate with absolute deionized water and ethanol once more. $\text{ZrO}_2$ Nanoparticles that modify by 4-MBA and PATP are similar to 4-MBA.

**Sample Characterization**

The crystal structure of the $\text{ZrO}_2$ sample was determined by X-ray diffraction using a Rikaug SmArtlab X-ray powder diffractometer with 0.15406 nm. The electronic absorption spectra were recorded on a Cary5000 UV-vis spectrophotometer. Raman spectra were obtained with Horiba HR Evolution Raman spectroscopy. The 532 nm radiation from an air-cooled argon ion laser was used as the exciting source. The morphology of $\text{ZrO}_2$ nanoparticles was characterized by the JEM-2000EX TEM instrument. A Thermo Fisher Escalab 250XI X-ray photoelectron spectroscopy (XPS) was applied to investigate the elemental composition and the surface electronic valence state for UPS.

**RESULTS AND DISCUSSION**

**$\text{ZrO}_2$ Phonon Modes (XRD & Raman)**

Zirconia has three low-pressure structural phases. With increasing temperatures, zirconia changes from a monoclinic phase ($m$-$\text{ZrO}_2$) to a tetragonal phase ($t$-$\text{ZrO}_2$), eventually becoming a cubic phase (Zheng et al., 2009). The monoclinic phase (space group C5 2h or P21/c) is thermodynamically stable at temperatures of $<$1400 K. At around 1400 K, the $t$-$\text{ZrO}_2$ transition (space group D15 4h or P42/ncm) is stable until 2570 K, and is a slightly distorted form of the cubic structure (Heuer et al., 1982). In this study, the size of the $\text{ZrO}_2$ nanoparticles was controlled by adjusting the calcination temperature to change the surface defect state of the nanoparticles to obtain a stronger SERS signal of the surface substance. This is verified by UV-vis spectra of $\text{ZrO}_2$ nanoparticles with different calcination temperature, see Figure S1.
Increase in Nanoparticle Size With Increasing Calcination Temperature

Figure 2A shows the XRD patterns of ZrO$_2$ nanoparticles calcined at different temperatures. The m-ZrO$_2$ is the dominant phase in these ZrO$_2$ nanoparticles. Almost all of the diffraction peaks are comparable to the standard data and are remarkably sharp, indicating the purity and high crystallinity of the synthesized ZrO$_2$ material. It can be observed that as the calcination temperature increases from 450 to 650°C, the XRD pattern becomes narrower and the sample crystallinity increases. The diameters of the ZrO$_2$ nanoparticles calcined at 450, 500, 550, 600, and 650°C were calculated from the full width at half-maximum using the Scherrer equation. The calculated diameters of the zirconia nanoparticles were 8.1, 10.5, 11.1, 15.5, and 17.6 nm, respectively. Thus, it can be seen that the grain size increases with increasing calcination temperature. The wide XRD peak is attributed to a very small particle size, which is also demonstrated by the transmission electron microscopy (TEM) results (Figure S2). As the calcination temperature increases from 450 to 650°C, both of the crystallinity and grain size of the ZrO$_2$ sample gradually increases. As shown in Figure S3, the XRD patterns show that the ZrO$_2$ nanoparticles calcined at 500°C primarily exhibit m-ZrO$_2$ (PDF card: 13-307), and there is extremely little t-ZrO$_2$ present (PDF card: 88-1007).

Nanoparticles Primarily Exist in the m-Phase

ZrO$_2$ samples were prepared through the sol-gel method and characterized using Raman spectroscopy (Figure 2B). The Raman shift characteristics reflect the energy level change in the specific vibration of the molecules. Tetragonal zirconia has six active vibrational modes (see Equation 1): B1g, Eg, B1g, Eg, A1g, and Eg (Zhao and Vanderbilt, 2002). Monoclinic zirconia has 18 Raman-active vibrational modes (see Equation 2).

$$\Gamma_{\text{vib}}^t = A1g + 2B1g + 3Eg$$  \hspace{1cm} (1)

$$\Gamma_{\text{vib}}^m = 9A1g + 9B1g$$  \hspace{1cm} (2)

From the Raman spectra and scattering data (see Figure 2B), it can be seen that the composition of the synthesized ZrO$_2$ is a mixture of t-ZrO$_2$ and m-ZrO$_2$, with a greater proportion of monoclinic phase. Comparing the Raman spectra, it is observed that the prepared ZrO$_2$ nanoparticles had an Eg vibrational mode at 265 cm$^{-1}$ corresponding to the tetragonal phase. The remaining peaks occurred at 221 cm$^{-1}$ (Bg), 309 cm$^{-1}$ (Bg), 332 cm$^{-1}$ (Bg), 345 cm$^{-1}$ (Ag), 380 cm$^{-1}$ (Ag), 476 cm$^{-1}$ (Ag), 503 cm$^{-1}$ (Bg), 539 cm$^{-1}$ (Bg), 558 cm$^{-1}$ (Ag), 613 cm$^{-1}$ (Bg), and 635 cm$^{-1}$ (Ag) are the vibration modes of m-ZrO$_2$ (Carlone, 1992). Figure 2B shows that the 11 active vibrational modes correspond well with the monoclinic phase. This indicates that m-ZrO$_2$ is dominant and the crystallization is relatively good. This point is consistent with the results observed using XRD; however, compared to the XRD patterns, the Raman spectra can reflect the difference in the crystallinity of ZrO$_2$ caused by different calcination temperatures with greater sensitivity.

Size-Dependent of SERS

ZrO$_2$ is an n-type semiconductor, and thus the surface of ZrO$_2$ nanoparticles are rich in oxygen vacancy defects (Navio et al., 2001). To study the effect of the calcination temperature of ZrO$_2$ on the SERS enhancement, SERS spectra of 4-MBA adsorbed on ZrO$_2$ nanoparticles calcined at different temperatures were obtained, as shown in Figure 3. The Raman spectra obtained for ZrO$_2$ nanoparticles at varying calcination temperatures can be used to explore the role of surface defects on the CT mechanism. For calcination temperatures in excess of 500°C, as the zirconia...
calcination temperature increases, the crystallinity also increases, resulting in a decrease in the surface defect content of the ZrO$_2$ nanoparticles (Figure 2A). This is also the reason for the decrease in CT effects of the ZrO$_2$ molecules. Therefore, it can be seen from Figure 3 that at temperatures above 500°C, the SERS signal of zirconia decreases with increasing temperatures. This indicates that in the process of ZrO$_2$ molecular CT, the surface defects play an important role and a rich surface state favors the ZrO$_2$-to-molecule CT process.

The structural characteristics of the ZrO$_2$ nanostructures are analyzed by TEM techniques, as shown in Figure S2. Based on the results, the crystalline sizes of all of the nanoparticles are $\approx 10$ nm in diameter, which is similar to the results obtained from the XRD patterns through calculation with the Scherrer equation. The results indicate that the size of the ZrO$_2$ nanoparticles increases with increasing calcination temperature. This indicates that the calcination temperature has a significant effect on the size of the nanoparticles. The optical properties of the ZrO$_2$ nanoparticles were further analyzed by means of UV-Vis spectra.

**Calculation of the Surface Enhancement Factor (EF)**

The surface enhancement factor (EF) was calculated for the 4-MBA adsorbed on ZrO$_2$ nanoparticles at an excitation of 532 nm. The assignment of each of the strong peaks in the Raman spectrum is listed in Table S1. The $\nu$ (C-C) ring breathing mode ($\sim 1,594$ cm$^{-1}$) was selected to calculate the EF of ZrO$_2$ nanoparticles. The EF calculation formula is shown in Equation (3):

$$EF = \frac{I_{\text{surf}} N_{\text{Bulk}}}{I_{\text{Bulk}} N_{\text{Surf}}}$$

where $I$ represents the corresponding intensity of the selected peak, and $N$ represents the number of molecules observed by the laser spot; $N_{\text{Bulk}}$ is the number of bulk 4-MBA molecules under laser irradiation, $N_{\text{Surf}}$ is the number of 4-MBA molecules involved in the surface modification of ZrO$_2$, $I_{\text{surf}}$ is the intensity of a vibrational mode in the SERS, and $I_{\text{Bulk}}$ is the intensity in the conventional Raman spectra of the same mode. From the area of
the laser spot (∼1.3 µm²) and the focus penetration depth of the laser (∼10 µm), the volume of the solid sample can be calculated. Based on the density (1.5 g·cm⁻³) and volume of 4-MBA, \( N_{\text{Bulk}} \) was calculated to be 7.61 × 10¹⁰. Assuming that a single layer of ZrO₂ nanoparticles are uniformly covered with a square centimeter of sediment, the number density is estimated to be 9.07 × 10¹¹ particles/cm² based on the XRD (according to the XRD results, the average diameter of the zirconia nanoparticles was 10.5 nm), as shown in Figure 2A. Using the laser spot size and the boundary density of the adsorbing molecules on the surface of the nanoparticles (∼0.5 nmol/cm²), \( N_{\text{Surf}} \) can be calculated as 6.15 × 10⁸. From the observed spectra, the ratio of intensities \( I_{\text{Surf}}/I_{\text{Bulk}} = 1765.42/5051.69 = 0.349 \) can be obtained. Substituting the obtained values for these variables into Equation 3, the EF value is calculated as 4.32 × 10³.

An enhancement (by a factor ∼3) of the Bg and Ag ZrO₂ phonon modes at 330 and 475 cm⁻¹, respectively, was also observed. This enhancement is similar to the enhancement mechanism for the normal mode of the molecule. The results show that an EF of more than 10⁴ is achieved for 4-MBA on ZrO₂ nanoparticles. It has not previously been reported that SERS signals are observed on the surface of ZrO₂, but the results are similar to the EF for other semiconductor nanoparticles that have been reported previously.

**CT Mechanism**

**a₁ and b₂ Modes of 4-MBA**

The SERS signal of a near-monolayer of 4-MBA adsorbed on the surface of ZrO₂ nanoparticles was observed (the excess of 4-MBA on the surface was washed away with a solvent). Figure 4 shows the Raman spectra for the bulk 4-MBA and a solution dissolved in ethanol (0.1 mol/L), as well as the enhanced Raman spectrum of 4-MBA on a ZrO₂ substrate. The only difference between the conventional Raman spectroscopy and SERS samples is the amount of 4-MBA molecules: in the former, a large number of pure 4-MBA molecules are present, while the latter utilizes a monolayer of 4-MBA molecules present only on the ZrO₂ substrate. All of the other test conditions and procedures are the same. A distinct 4-MBA signal was observed on the ZrO₂ substrate with clear Raman peaks at 1075, 1146, 1181, and 1594 cm⁻¹. However, because SERS modifies the surface selection rules, there is a significant difference in the relative intensities of the peaks observed for the 4-MBA molecule in the Raman and SERS spectra. The bulk 4-MBA spectrum is mainly dominated by the fully symmetric a₁ vibration mode, while the SERS spectrum for 4-MBA exhibits a strong contribution of the asymmetric b₂ mode (1146 cm⁻¹).

The Raman peak at 1075 cm⁻¹ is attributed to aromatic ring vibration with a C-S stretching mode (ν12a, a₁), while at approximately 1,594 cm⁻¹ the Raman peak is assigned to the aromatic ring breathing mode (ν8a, b2). As shown in Figure 4, the Raman spectrum for 4-MBA adsorbed on the surface of zirconia nanoparticles was strongly enhanced compared to the conventional Raman spectrum for 4-MBA, and the Raman shift was significantly different from that of the bulk Raman spectrum. The spectrum of the 4-MBA adsorbed on the surface of zirconia nanoparticles exhibits a weak peak at 1146 cm⁻¹ (ν15, b2) in the SERS spectrum (attributed to the C-H deformation vibrational mode), which is generally considered to be due to the Herzberg-Teller contribution that produces enhanced CT effects. The SERS spectrum of 4-MBA on the surface of ZrO₂ is almost identical to that observed on the surface of ZrO₂ and TiO₂ in the literature. We also calculated the value of P_{CT}, which was calculated through the expression which was defined as “P_{CT} = R/(1 + R)” for the degree of charge transfer(R = I₂b₂/I₄a₁).

As shown in Figure S4, the P_{CT} of 4-MBA is near 0.5 at the excitation wavelengths of 532, 633, and 785 nm. It was observed that the degree of charge transfer increases with the increase of laser energy.

**Direction of CT Effects**

There are two main ways to explain the enhancement mechanism of the SERS effect: chemical mechanisms (CT) and electromagnetic mechanisms (EM). Chemical enhancement (CE) is a resonance-like Raman process. It is generated by chemical adsorption interactions between the substrate and the adsorbed molecules and photoinduced charge transfer, resulting in an increase in the polarizability and an increase in the distribution number of the adsorbed molecules in the excited state. The electromagnetic mechanisms (EM) is caused by an increase in the local electric field induced by the laser on the surface of the nanoparticles (Kadkhodazadeh et al., 2014; Mogensen and Kneipp, 2014). According to the literature, for most semiconductor materials, the surface plasmon resonance frequency is in the infrared region, away from the excitation wavelength (532 nm) used to obtain the SERS phenomenon in this study (Wang et al., 2009; Xue et al., 2012). Therefore, the SERS enhancement of ZrO₂ in this work does not include EM contributions, but mainly contributes to CE contributions. In Figure 4, the SERS spectrum of 4-MBA exhibit a non-totally symmetric b₂ mode at 1146 cm⁻¹. As the CT mechanism is a resonance Raman-like process, the charge transfers occurred between the ZrO₂ nanocrystals and 4-MBA molecules. When
the organic molecules and semiconductor are in contact with each other, a reasonable charge distribution will exist around the interface within a very short time. A new electronic state then forms at the interface.

To determine the direction of charge transfer in the 4-MBA–ZrO$_2$ complex, Gaussian 09 was used to calculate the highest occupied molecular orbital (HOMO) and lowest unoccupied molecular orbital (LUMO) of 4-MBA adsorbed on ZrO$_2$ nanoparticles, as shown in Figure 5A. In the 4-MBA-modified ZrO$_2$ system, the HOMO and LUMO for the 4-MBA occur at $-6.75$ and $-1.33$ eV, respectively. Thus, the CT between ZrO$_2$ and the adsorbed 4-MBA molecule may occur as shown in Figure 5B. In these experiments, when irradiated under a 532 nm (ca. 2.33 eV) laser, the excited electrons of the ZrO$_2$ conduction band (CB) migrate to the LUMO of the adsorbed molecules. This is a reasonable CT model to explain the SERS of ZrO$_2$ modified by 4-MBA.

Zhao et al. reported the use of UV-Vis diffuse reflectance spectroscopy (DRS; Figure S5) (Zhang X. et al., 2015) and ultraviolet photoelectron spectroscopy (UPS; Figure S6) to calculate the HOMO and LUMO of the substrate and probe molecules. This can be calculated with Equation 4:

$$W = h\nu - \Delta E$$

(4)

The value of $h\nu$ is 21.22 eV, and thus the valence band (VB) of ZrO$_2$ is calculated to occur at $-5.19$ eV. The band gap of ZrO$_2$ is 4.95 eV, and the CB of ZrO$_2$ is situated at $-1.97$ eV. As shown in Figure 5B, in the ZrO$_2$ system modified by 4-MBA, the HOMO of the 4-MBA is at $-6.24$ eV and the LUMO is at $-1.68$ eV. Therefore, considering the relative band structure of the ZrO$_2$ system with 4-MBA, the CT direction between the ZrO$_2$ and 4-MBA determined by the theoretical calculations and UPS results is consistent, i.e., the CT occurs from the zirconium dioxide to the 4-MBA molecules.

**SERS Spectra of the ZrO$_2$ Surface Modified by 4-MBA, 4-MPY, and PATP**

To illuminate that the enhancement mechanism of a ZrO$_2$ surface modified by 4-MBA is the CT mechanism, the following experiment was performed. The surface of ZrO$_2$ nanoparticles were modified with different thiophenol-related molecules (4-MPY and PATP), as shown in Figure 6A. In addition, these thiophenol-based molecules possess functional groups on the benzene ring, such as C-COOH, N, or C-NH$_2$. The electron attracting ability of these functional groups on the benzene ring occurs in the order of C-COOH (4-MBA) > N (4-MPY) > C-NH$_2$ (PATP). Figure 6A shows the SERS spectra for 4-MBA, 4-MPY, and PATP adsorbed on ZrO$_2$ nanoparticles. The results clearly show that the intensities decrease in the order of 4-MBA > 4-MPY > PATP. This is in agreement with the previous estimations.

As the probe molecules have almost the same Raman cross-sections, the experimental results described above are not due
to different Raman cross-sections of the molecules. The SERS spectra effect is consistent with the ability of the mercapto-pair to attract electrons. These results indicate a correlation between the SERS signal and the ZrO$_2$-to-molecule CT. This suggests that for ZrO$_2$ nanoparticles surface-modified by other molecules, the primary enhancement mechanism is the CT mechanism. The stronger the electron-withdrawing groups in the molecules bonded on the surface of ZrO$_2$, the greater the ability of ZrO$_2$ for molecular CT will be, and a stronger SERS signal on the ZrO$_2$ will be observed.

Comparisons of the optical properties of ZrO$_2$ nanoparticles modified by molecules with those of pure ZrO$_2$ were carried out by using UV-Vis spectroscopy (Figure 6B). It is clear that the adsorption of organic molecules has a significant influence on the absorption spectrum of ZrO$_2$. It was observed that the typical ZrO$_2$ direct band gap adsorbs organic molecules with different degrees of narrowing and widening.

Figure 55 shows the spectra of ZrO$_2$ nanoparticles surface-modified by 4-MBA, 4-MPY, and PATP, as well as pure ZrO$_2$ nanoparticles monitored with room temperature UV-vis DRS. Using the Kubelka–Munk function, the bandgap energy of the pure ZrO$_2$ and molecule-modified ZrO$_2$ were calculated based on the photon energy $[\alpha(E)]^2$ function. The resulting band energy is 4.95 eV (250 nm) for the pure ZrO$_2$ nanoparticles, 3.22 eV (385 nm) for the 4-MBA-modified ZrO$_2$, 4.88 eV (254 nm) for the 4-MPY-modified ZrO$_2$, and 4.91 eV (253 nm) for the PATP-modified ZrO$_2$. The interaction between the adsorbed molecules and the ZrO$_2$ nanoparticle substrate resulted in these shifts. The transformation may be due to the interaction of the nanoparticles with probe molecules. The observed shift shows that the bandgap of the 4-MBA-ZrO$_2$ system has a lower optical transition energy than that of pure ZrO$_2$ due to the CT transition. The 4-MBA-ZrO$_2$ system has the lowest optical transition energy, which explains why the ZrO$_2$ modified by 4-MBA has the strongest SERS effect.

CONCLUSION

This study first observed that the SERS spectrum can be obtained on the surface of ZrO$_2$. The results show that the SERS spectrum of 4-MBA on ZrO$_2$ is mainly due to the contribution of the CT mechanism, and the intrinsic properties of the adsorbed molecules and the surface properties of the semiconductor have a significant effect on SERS. The plentiful surface state of the ZrO$_2$ active substrate is beneficial for the occurrence of CT resonance between molecules and the ZrO$_2$ to produce a SERS effect. The results show that the ZrO$_2$ nanoparticles prepared through the sol-gel method at a calcination temperature of 500°C exhibit the strongest SERS effect on the surface-adsorbed probe molecules. This study demonstrates for the first time that ZrO$_2$ can be used as a Raman enhancement substrate material, breaking through the limitations of the precious metal substrates used in traditional SERS technology, and further broadening the application of semiconductor oxides as substrate materials for SERS detection. Also, the SERS study on the size effect of nano-sized ZrO$_2$ is expected to promote the better performance of nano-ceramic materials to enable the emergence of new properties and functions.
