When suspended particles are pushed by liquid flow through a constricted channel they might either pass the bottleneck without trouble or encounter a permanent clog that will stop them forever. But they might as well flow intermittently with great sensitivity to the neck-to-particle size ratio $D/d$. In this work, we experimentally explore the limits of the intermittent regime for a dense suspension through a single bottleneck as a function of this parameter. To this end, we make use of high time- and space-resolution experiments to obtain the distributions of arrest times between successive bursts, which display power-law tails with characteristic exponents. These exponents compare well with the ones found for as disparate situations as the evacuation of pedestrians from a room, the entry of a flock of sheep into a shed or the discharge of particles from a silo. Nevertheless, the intrinsic properties of our system seem to introduce a sharp transition from a clogged state (power-law exponent below two) to a continuous flow, where clogs do not develop at all. This contrasts with the results obtained in other systems where intermittent flow, with power-law exponents above two, were obtained.

When people, animals, or particles are forced through a constriction, the flow may become intermittent due to the development of clogs that obstruct the constriction. Despite the diverse nature and scale of these systems – including hungry sheep herds [1, 2], pedestrian crowds trying to escape a room in a life-and-death situation [3, 4], discharge of dry granular silos [5–8], suspended hydrated particles transported through pipelines [9], electrons passing through nanoconstrictions on a liquid helium surface [10], sand hourglass [11], or mice escaping a water pool [12] – a distinctive phenomenology of particles or bodies flowing in erratic bursts is observed, separated by short period of arrest. The analogy does not seem to be only qualitative: in all cases the number of escapees per burst follow an exponential distribution, and the probability distribution of time lapses separating the passage of consecutive bodies seems to exhibit a power-law tail with characteristic exponents that depend on diverse system parameters. These common features lead Zuriguel et al. to propose a unified description [1], providing a general framework for the study of intermittent clogging systems.

Among the different driving forces pushing entities through bottlenecks, the drag imposed by liquid flow is particularly interesting for small particles. Consequently, one can find several recent studies on the flow of constricted suspensions [13–16] with applications to drug delivery [17], lifetime reduction of filters in separation processes [18], pollutants removal using subsurface treatment [19], or in technological applications relying on the suppression of any kind of blockage such as inkjet printing [20]. The addressed question often concerns clogging prevention, nonetheless the clogging itself can also be advantageous, like in medicine to provoke embolization of blood vessels in order to shrink a tumor [21]. Interestingly, in spite of these numerous studies, the limits of the clogging/flowing regimes of constricted particle suspensions has received little attention, with some exceptions in other similar configurations [22] or

Figure 2. Spatio-temporal diagrams at the constriction neck for various $D/d$. For $D/d \leq 2.43$ only few particles (which appear in dark) escape before a permanent clog is formed. When increasing $D/d$, intermittent particle flow is observed, eventually reaching particle continuous flow for $D/d \geq 5.26$.

using numerical simulations [23]. It is indeed a complex task to tackle experimentally given the requirement of high-reproducibility, high time-resolution and large data sets for good statistics. The problem is however crucial since it would clarify the role of the driving force, and in this case, the effect of the interstitial fluid in the clogging/unclogging process, which is a matter of current active debate [24–26]. In this work, we explore the critical sensitivity of the intermittent particle flow on the neck-to-particle size ratio $D/d$ by using high-resolution and high-speed optical video microscopy.

A schematic of the experimental set-up is shown in Figure 1a. The fluidic system consists of a transparent straight channel of borosilicate glass (isotropic wet etching fabricated by Micronit microfluidics) of uniform thickness 100 $\mu$m, which is locally constricted in the middle. The constriction is achieved by a linear narrowing of the channel with a half-angle of $60^\circ$ from the nominal width of 400 $\mu$m down to 110 $\mu$m at the neck. This specific design, similar of that used in Marin et al. [26], forms a two-dimensional nozzle converging towards the almost squared cross-section of the neck (110 x 100 $\mu$m$^2$). Particles and liquid have been carefully chosen to ensure a flow without buoyancy effects and in the absence of both particle aggregation or particle deposition on the wall of the micro-channel, as other studies have previously analyzed [13, 27]. The suspension consists of monodisperse polystyrene particles of diameter $d$ which is varied from 19.0 to 41.1 $\mu$m (see table I). Particles are stabilized with negatively charged sulfate groups (Microparticles GmbH) in a density-matched 26.3 wt% aqueous solution of glycerine, with a density $\rho = 1062$ kg/m$^3$ and a viscosity $\mu = 2.1$ mPa.s. The charged sulfate groups confer them a small negative surface potential (on the order of $-50$ mV) but sufficient to prevent both their agglomeration and their adhesion to the channel walls. The suspension is driven through the constriction at constant volume flux using a syringe pump (Harvard Apparatus), at a Reynolds number $Re = \rho \langle U \rangle d/\mu \sim 10^{-3}$ (corresponding to particle velocities $\langle U \rangle \approx 5$ mm/s). The average particle velocity at the constriction neck $\langle U \rangle$ is used to define the Stokes time $\tau = d/\langle U \rangle$ (the time a particle takes to travel its own diameter), which will be used as the characteristic time scale. The reason for using such particle size range (between 10 and 50 $\mu$m) is dual: on the one hand, we avoid colloidal particle interactions and Brownian motion. On the other hand, increasing the particle size also involves the flow control of larger volumes of fluid and higher working pressure. Therefore, the range of particle size chosen allows us to work with highly monodisperse particles interacting mainly by lubrication interactions and low-pressure solid contacts, manipulated via microfluidic technology, which allows us to obtain a high degree of control and reproducibility difficult to achieve at other length scales. The suspension is prepared with a particle volume fraction of about 2%, then inserted in the device and driven downstream the constriction to a filter which only allow the fluid to flow through. Particles therefore locally accumulate downstream the constriction.

The experiment starts when the flow is reversed and particles are dragged by the fluid towards the constriction. The particle volume fraction as the particle reach the constriction is $\approx 60\%$, and the suspension is imaged with a high-speed CMOS camera (PCO.dimax CS1, 12 bit, 1000fps) coupled to an inverted microscope (Nikon Instruments, Eclipse TE2000-U). Figure 1b presents successive snapshots of a typical intermittent flow experience.
(see also Movie 1). In particular, the flow becomes interrupted by the spontaneous formation of arches spanning the bottleneck (top panel in Figure 1b). At this moment, the fluid keeps passing through the particles interstices perturbing the arches which may eventually collapse. If this happens, the flow of particles is resumed (middle panel in Figure 1b) and a burst develops until a new clog arrests the flow again (bottom panel). It is important to note that arches are stabilized by the mutual friction among particles, implying that despite electro-static stabilization particle-to-particle contact is unavoidable in our system. However, these contacts are not long-lasting as particles separate downstream the constriction upon resuming the flow.

The overall intermittent behavior, in which several flow and arrested periods of time alternate, can be better visualized in the spatio-temporal diagrams in Figure 2. There, in order to analyze the different regimes of particle flow, we report the results obtained for particle diameters \( \bar{d} = 41.1, 33.9, 28.6, 25.1, 21.7 \) or 19.0 \( \mu \text{m} \) (±3%). Adopting the neck height \( D = 100 \mu \text{m} \) as the characteristic length scale, these correspond to neck-to-particle ratios \( D/d = 2.43, 3.03, 3.3, 3.99, 4.61, \) and 5.26, respectively (see table 1). Note that a spatio-temporal diagram is constructed by selecting a vertical line of unit pixel width at the middle of the constriction. This line is then sampled for every frame and is stacked alongside (see also Movie 2). The diagrams clearly reveal a qualitative difference in the flow behavior: from a blocked situation (top diagram) to uninterrupted particle flows (bottom diagram). For \( D/d \leq 2.43 \) only few particles (which appear in dark) escape before a clog is formed. As \( D/d \) is increased, the intermittent particle flow regime emerges and the flowing intervals become longer and more abundant. This regime persists until the flow becomes continuous, so the bursts intermittency becomes unmeasurable. Note that in this system, the intermittent flow is only observed for \( 2.43 < D/d < 5.26 \). We must emphasize that with a similar setup, Marin et al. [26] reported continuous flow for neck-to-particle size ratio down to \( D/d = 4 \).

Although their observation was not based on a systematic study, it is consistent with the results reported here if we consider that the constriction angle in their setup was smaller (45°) than the one consider here (60°). In a silo full of dry grains, reducing the hopper angle (with respect to the vertical direction) has been shown to decrease clogging probability in such quantitative way [7, 28].

In what follows, we will quantify the intermittent dynamics by analyzing separately the clog formation and clog destruction processes by looking at the statistics of burst sizes and arrest times respectively.

**Clog development.** In this particular system, the formation of arches has been described using a simple stochastic model [26], considering that an arch develops when a sufficient number of randomly arriving particles reach the constriction in the appropriate arrangement (see an example of a minimalistic arch formation on Movie 3). Similarly, Thomas and Durian [29] proposed a model for dry systems in which they showed that the discharged particle mass grows as an exponential function of hole diameter. Both models are actually compatible with the idea that new microstates [29] in the vicinity of the constriction are continuously and randomly sampled while particles arrive, until a stable arch is eventually found. One consequence of such clogging mechanism contemplated by both models is that there is no sharp clogging transition for a given critical outlet size in the sense that there is always a non-zero probability for a clog to occur.

It is therefore important to test the stochasticity of the particle bursts: Particle clogs should occur randomly with the same probability for all particles to get trapped; consequently the number of particles per bursts should follow an exponential distribution as it does in avalanches or fractures occurring stochastically [30]. It is then expected that the distribution of particle number per burst follows an exponential distribution, as it is well-known for particles in silos [6], Brownian [23] and non-Brownian suspensions [26], pedestrians [31] and animal flocks [2], regardless of the stability of the arch that separates each particle burst (permanent or intermittent). Experimentally, monitoring the number of particles per burst is not a trivial task given that particles overlap frequently in this three dimensional configuration. Measurements were done for one particular case of low \( D/d (= 3.03) \), for which the amount of overlaps is lower and the tracking is more effective. A particle tracking algorithm was specially developed to accurately track every escaping particle. This method is based on a Kalman filter [32] and al-

![Figure 3. Distribution of the normalized number of escaped particles \( s/\langle s \rangle \) and burst duration \( T_b/\langle T_b \rangle \) for \( D/d = 3.03 \), for which \( s = 270 \) and \( T_b = 55\tau \). The dashed-line corresponds to an exponential fit. Inset: Typical particle burst showing the particle tracking employed for counting individual particles. The colors code for particles escaping during the same burst.](image-url)
lows precise prediction of the expected position of tracked particles over several frames where particles are partially or totally occluded by neighboring particles, making it particularly efficient for tracking relatively dense flow of particles, as illustrated in the inset of Figure 3 (see also Movie 4).

Note also that given the discrete nature of the system, defining a arrest time threshold to set apart successive bursts is not straightforward. This is done by looking at the distribution of times between the passage of two consecutive particles (as it will be shown below). From those distributions, and using the Clauset-Shalizi-Newman method [33], a characteristic minimum time is obtained $T_{\text{min}}$. Then, a flow interruption longer than $T_{\text{min}}$ implies the end of a burst and the beginning of another.

Figure 3 shows the distribution of the burst size $s$ normalized by the mean burst size $\langle s \rangle$. The distribution is well fitted by an exponential distribution, which can be explained assuming there is a constant probability of clogging during the whole burst [6]. It is nonetheless surprising to find a substantially higher probability for the smallest particle bursts in the distribution. This means that, relatively often, small number of particles (of the order of $\sim \langle s \rangle/10$) manage to escape from an arch without destabilizing it. We interpret this feature as a result from the system’s inherent three-dimensionality, as such behavior is not reported for two-dimensional configurations. Importantly, although the choice of a different threshold $T_{\text{min}}$ obviously affects the particular value of $\langle s \rangle$, we have checked that the shape of the distribution is unaffected.

Apart from analyzing the burst size distributions (in number of beads) we have also computed the burst duration $T_b$ which is defined as the lapse time going from the passage of the first particle of the burst to the last one. As expected, the distributions of $T_b$ display the same features than described before; i.e. an exponential tail with a notably higher probability for short burst durations. This confirms that these two parameters are equally suitable to describe clogging development as a Poisson process.

**Clog destruction.** In order to investigate the unclogging dynamics, the probability distributions of the time lapses $T$ between the passage of consecutive particles are analyzed. We follow here the same strategy implemented in previous studies on intermittent flowing systems, like hungry sheep herds [2], pedestrian crowds [3, 4, 31], mice escaping a water pool [12], or vibrated silos of dry granular material [5, 34]. In such systems, it has been found that the distribution of arrested time lapse exhibits a power-law tail $P(T) \propto T^{-\alpha}$, thus being a signature of systems prone to clogging [1]. Furthermore, the value of the exponent $\alpha$ is proxy for the intermittency of the particle flux. Note that average time lapses $\langle T \rangle$ can only be defined for distributions fulfilling $\alpha > 2$, while $\langle T \rangle$ diverges for $\alpha \leq 2$, which we interpret as a transition to a scenario in which a permanent clog will eventually develop. For $\alpha \leq 2$, there is a non-zero probability of observing persisting clogs which last forever, while for $\alpha > 2$, the system can be temporary blocked due to the formation of clogs but no arch will persist infinitely. From our data, the exponent $\alpha$ of the power-law tail is obtained using the rigorous Clauset-Shalizi-Newman method [33], which also yields the goodness of the fit, and gives the minimum time lapse $T_{\text{min}}$ from which the power-law fit is valid (this is, indeed, the time lapse used to set apart consecutive bursts that was mentioned before).

Figure 4 presents the probability distribution of the arrest times normalized by the Stokes time $T/\tau$. The lines correspond to the best power law fits with their exponent $\alpha$, as given by the Clauset-Shalizi-Newman method [33]. Inset: $\alpha$ as a function of the neck-to-particle size ratio $D/d$. The exponent can only be defined when the flow is intermittent and the values obtained (always below 2) reveal that the system is in the clogged regime when $D/d < 5.26$. See values of $\alpha$ in table I.

| D/d        | 2.43 | 3.03 | 3.50 | 3.99 | 4.61 |
|------------|------|------|------|------|------|
| d (µm)     | 41.1 | 33.0 | 28.6 | 25.1 | 21.7 |
| $\alpha$   | Permanent clog | 1.46 | 1.48 | 1.84 | 1.94 |

Table I. Values of $\alpha$ for various neck-to-particle size ratios.
Stokes time. Furthermore, around 800 bursts have been analyzed for each neck-to-particle size ratio. Overall, our measured time-lapse distributions yield tails spanning at least over 3 orders of magnitude for the largest \( D/d \) and up to 4 orders of magnitude for the smallest \( D/d \).

As shown on the inset of Figure 4, where \( \alpha \) is plotted versus \( D/d \), the exponent is remarkably sensitive to the neck-to-particle size ratio. Indeed, it goes through an abrupt increase in the range \( D/d = 3.50 \) to 3.99, from \( \alpha = 1.47 \pm 0.03 \) up to \( 1.84 \pm 0.07 \). We want to stress the high sensitivity of the system on such a small increase on \( D/d \), since it represents only a decrease in about 10\% on the particle size (about 3 microns of decrease in the particle diameter). Remarkably, for the neck to particle sizes for which time lapse distributions were measurable, the value of \( \alpha \) exclusively remains below 2, thus indicating a non-zero probability of observing clogs that persist indefinitely. The trend clearly suggests that the expected value for \( D/d = 5.26 \) would lay within the area of \( \alpha > 2 \) (non-persistent clogs). However, in this case the flow is uninterrupted, at least at the experimental time scale. This feature indicates that for \( D/d \) around 5, a sharp transition occurs from a clogged state (intermittent flow with \( \alpha \leq 2 \)) to a continuous flow (zero probability of clogging or negligible in practical terms). As far as we know this is a unique property of our system. In fact, in all the other scenarios where the unclogging transition has been reported based on the power law tails of the clogging times (vibrated silos [5], simulated colloids or pedestrians [1], and self propelled robots [35]), the passage from clogged state (\( \alpha \leq 2 \)) to continuous flow, occurred through a region of intermittent flow with \( \alpha > 2 \). The fact that this regime is not observed in our case may be just a consequence of the intermittent region being very narrow; but it can also reflect that the perturbation introduced by the fluid is not high enough to destroy the strongest arches formed in each experimental condition.

To conclude, we have shown that volume-driven flow of dense non-adhesive colloidal particle suspension going through a constriction exhibits intermittent flow behavior with a striking similarity as in dry granular matter, human crowds, or animal herds [1], which we have proved in this work in a quantitative manner. At low Reynolds number and in the absence of particle aggregation or particle/wall adhesion, the geometry of the system (neck-to-particle size ratio and constriction angle) prescribes the flow regime entirely. At low \( D/d \) the flow is quickly interrupted by the formation of stable particle arches spanning the constriction, while at large \( D/d \) the flow is continuous and no stable arches develop (at least in the experimental timescale). A transitioning intermittent regime is reported for \( 2.43 < D/d < 5.26 \), for which we have investigated the distribution of the time lapse \( T/\tau \) between the passage of consecutive particles. The distribution displays a characteristic power-law tail \( \propto (T/\tau)^{-\alpha} \) with values of \( \alpha \) below two in all cases. This unexpected result implies that, according to the definition given in [1], our system will exhibit a transition from a clogged state to a continuous flow for \( D/d \) around five.
