**Abstract**

Granulosa cell tumours of the ovary are rare, comprising around 3% of ovarian tumours. These tumours have preponderance for local spread and extremely late recurrence. Although previous cases of recurrence have been described, it is extremely unusual for these tumours to recur after thirty years. We describe a case of recurrence of granulosa cell tumour after 30 years, presenting as small bowel obstruction. The patient had not been followed up after the original surgery, and on histological analysis, recurrence of the original tumour was confirmed. This case report emphasises the necessity for lifelong follow-up of patients who have had these tumours excised, and also the unusual way in which these tumours can recur.

**Introduction**

Granulosa cell tumours are uncommon sex cord-stromal tumours of the ovary, and comprise approximately 3% of all ovarian malignancies [1]. These tumours characteristically have a low malignant potential, and a tendency for local spread and high recurrence rates, sometimes many years after the original diagnosis [2,3].

We describe a case of granulosa cell tumour of the ovary, which recurred many years after the original surgery. Whilst there have been reports of recurrence of this tumour, recurrence after 30 years is extremely rare [4,5]. Moreover, to our knowledge, this is the first described case manifesting as small bowel obstruction.

**Case Report**

A 72 year old female was admitted from the emergency department with a five day history of abdominal pain, and markedly abnormal blood tests; haemoglobin 8.1 g/dl, white count $11.2 \times 10^6$ /dl, urea 28.3 mmol/l, creatine 409 µmol/l. Physical examination revealed a large abdomen, non-distended, with diffuse tenderness, no guarding and normal bowel sounds.

Her past medical history was significant in that she was under haematological review for chronic normocytic, normochromic anaemia. This had been present for at least 20 months, and had been investigated with upper and lower gastrointestinal tract endoscopy, blood tests and ultrasound scanning all of which had been unremarkable.

There had also been one previous admission for acute abdominal pain 30 years earlier, and she had undergone laparotomy on the night of admission. Surgery revealed an enlarged right ovary with multiple solid areas, with rupture into the broad ligament. A total hysterectomy and bilateral salpingo-oophorectomy were performed. Histology revealed a mainly solid, large granulosa cell tumour of the ovary, with acute rupture. She was discharged uneventfully, and had not been followed up.
In the current admission, she was admitted for further investigation, and underwent an abdomino-pelvic contrast CT scan the next day. This revealed a large pelvic mass causing compression of the right ureter, and a right hydronephrosis (Figure 1, arrow).

The next day, she developed nausea, vomiting and colicky abdominal pain, and a plain abdominal radiograph was ordered. This revealed dilated small bowel loops, and a diagnosis of small bowel obstruction was made (Figure 2). She did not respond to conservative management, and developed signs of small bowel strangulation after 24 hours.

At laparotomy, the terminal ileum was gangrenous in several places, and found to be tethered to a focal organised haematoma arising from a large retroperitoneal cystic mass behind the bladder. There was no blood elsewhere in the abdominal cavity.

The retroperitoneal mass was incised, with the resulting release of a haematoma of around 1 litre in quantity. This was evacuated from the cyst, together with a necrotic lesion in its centre, and sent for histology. A small bowel resection was performed, drains inserted and the abdomen closed.

She made an uneventful recovery, with full resolution of her renal function, and anaemia.

Subsequent histology revealed a sex cord – stromal tumour of ovary, characterised as a poorly differentiated granulosa cell tumour. The small bowel was also involved by tumour. An immunohistochemical review of her original tumour from thirty years prior was performed, and confirmed that a recurrence of the original lesion had occurred.

She was referred to a specialist oncological centre for further management and presently remains asymptomatic and disease-free.

Discussion
The tendency for late recurrence makes granulosa cell tumours unique amongst malignant ovarian tumours. It is thought that recurrent tumours arise from peritoneal seeds which begin at a point of contact between the primary tumour and a lower abdominal or pelvic structure [6]. These lesions then remain after surgical excision of the primary tumour, and grow extremely slowly as discrete masses, displacing adjacent structures and organs, but only infrequently invading them. Overall time to recurrence from initial surgery varies greatly. On review of the literature, our case is the second reported case of recurrence after 30 years [5].
follow-up. Patients who have been given this diagnosis have lifelong presentation. It is imperative that the original diagnosis. Moreover, recurrent tumours can occur many years after the treatment. Granulosa cell tumours can occur many years after the initial presentation, and these tumours can present with unexpected symptoms. It is imperative that the terminal ileum to the adjacent organ that is intra-abdominal haematoma resulted in small bowel obstruction.

At her original surgery, our patient was found to have a large tumour, which had acute rupture. Histology did not reveal any untoward prognostic features.

Predictors for recurrence may include advanced stage at presentation, high tumour mitotic count, bilaterality, large tumour size, tumour rupture, and lymphatic space invasion [11-13], although other studies have refuted the correlation of these criteria with risk of relapse [14]. More recently, molecular markers such as Ki-67 and p53 overexpression have been linked to a higher recurrence risk and poor survival [15]. The polypeptide hormone inhibin may be useful as a marker for the diagnosis of recurrent tumours. Inhibin is produced by granulosa cells, and should be absent in the oophorectomised, post-menopausal female [16]. In one prospective study, serum inhibin levels became elevated up to 2 years before surgery was performed for recurrent disease [17].

Recurrent tumours can be treated with surgical resection, post-operative chemotherapy or radiotherapy. Surgery is considered palliative, and repeated surgical debulking has been described as a successful method of controlling symptoms and prolonging survival [1]. Although combination chemotherapy regimens with cisplatinum, vinblastine and bleomycin (PVB) have demonstrated response rates of over 90%, impact on disease-free and long-term survival is currently unknown.

The relatively small numbers of patients available for study together with the fact that recurrences may occur extremely late has meant that randomised controlled trials to assess the relative effectiveness of surgery over chemotherapy or radiotherapy are not feasible.

In conclusion, this report reiterates that recurrence of granulosa cell tumours can occur many years after the original diagnosis. Moreover, recurrent tumours can present with unexpected symptoms. It is imperative that patients who have been given this diagnosis have lifelong follow-up.
