Background: AMPK is implicated as the mediator of AICAR action on liver metabolism. AMPK suppresses glucose production independent of AMPK. Regulation of mitochondrial function is AMPK-dependent.

Results: AICAR suppresses glucose production independent of AMPK. Regulation of mitochondrial function is AMPK-dependent.

Conclusion: Nucleotide monophosphates rely on AMPK to regulate energy metabolism but not to suppress glucose production.

Significance: Targeted AMPK activation will not lower glucose production in metabolic diseases but could improve hepatic energetics.

Metabolic stress, as well as several antidiabetic agents, increases hepatic nucleotide monophosphate (NMP) levels, activates AMP-activated protein kinase (AMPK), and suppresses glucose production. We tested the necessity of hepatic AMPK for the in vivo effects of an acute elevation in NMP on metabolism. 5-Aminoimidazole-4-carboxamide-1-β-D-ribofuranoside (AICAR; 8 mg·kg−1·min−1)-euglycemic clamps were performed to elicit an increase in NMP in wild type (α1α2lox/lox) and liver-specific AMPK knock-out mice (α1α2lox/lox + Albcre) in the presence of fixed glucose. Glucose kinetics were equivalent in 5-h fasted α1α2lox/lox and α1α2lox/lox + Albcre mice. AMPK was not required for AICAR-mediated suppression of glucose production and increased glucose disappearance. These results demonstrate that AMPK is unnecessary for normal 5-h fasting glucose kinetics and AICAR-mediated inhibition of glucose production. Moreover, plasma fatty acids and triglycerides also decreased independently of hepatic AMPK during AICAR administration. Although the glucose regulatory effects of AICAR were shown to be independent of AMPK, these studies provide in vivo support for the AMPK energy sensor paradigm. AICAR reduced hepatic energy charge by ~20% in α1α2lox/lox, which was exacerbated by ~2-fold in α1α2lox/lox + Albcre. This corresponded to ~6-fold rise in AMP/ATP in α1α2lox/lox + Albcre. Consistent with the effects on adenine nucleotides, maximal mitochondrial respiration was ~30% lower in α1α2lox/lox + Albcre than α1α2lox/lox livers. Mitochondrial oxidative phosphorylation efficiency was reduced by 25%. In summary, these results demonstrate that the NMP capacity to inhibit glucose production in vivo is independent of liver AMPK. In contrast, AMPK promotes mitochondrial function and protects against a more precipitous fall in ATP during AICAR administration.

The gluco-regulatory system of the body coordinates glucose supply and demand with such precision that arterial glucose is maintained within narrow limits. Research has provided a clearer understanding of the hormonal and interorgan communication required for normoglycemia in vastly different physiological conditions (1). Indeed, disruption of this sensitive regulatory system has had a broad impact on public health (2). The alarming prevalence of diabetes and associated metabolic disorders means the mechanistic understanding of glucose homeostasis imperative.

AMP-activated protein kinase (AMPK)2 is a conserved, heterotrimeric serine/threonine kinase composed of α, β, and γ subunits (3). AMPK senses a decrease in cellular energy and responds by triggering pathways that work to maintain energy balance (3). Furthermore, ADP and AMP bind the AMPK γ subunit, which primes the enzyme for αThr172 phosphorylation and protects against dephosphorylation. Phosphorylation increases AMPK activity, which is further stimulated by allosteric AMP activation (4). Removal of LKB1, the primary kinase responsible for AMPK phosphorylation in the liver, blunts AMPK activation and, interestingly, results in severe hyperglycemia (5). AMPK has been invoked as the major mediator of the suppressive effects of biguanides, 5-aminoimidazole-4-carboxamide-1-β-D-ribofuranoside (AICAR), and a number of endocrine factors on hepatic glucose production. However, recent

2 The abbreviations used are: AMPK, AMP-activated protein kinase; AICAR, 5-aminoimidazole-4-carboxamide 1-β-D-ribofuranoside; NMP, nucleotide monophosphate; FCCP, carbonyl cyanide-p-trifluoromethoxyphenylhydrazone; EC, energy charge; GIR, glucose infusion rate; EndoRa, endogenous glucose production; Rd, glucose disappearance; TG, triglyceride; ACC, acetyl-CoA carboxylase.
studies in genetic models dispute the necessity of hepatic AMPK for the acute effects of some anti-glycemic agents (6–8). Adding yet another layer of complexity to the enigmatic role of AMPK in glycemic control, AMPK activation is highest in physiological conditions characterized by elevated glucagon action and hepatic glucose production (9–11).

AMPK activation correlates with endocrine and energetic states characterized by pro-oxidative, anti-lipogenic signaling in the liver (9–14). Evidence supports a role for AMPK in regulating fat utilization and mitochondrial function in the liver (15–17). Furthermore, AICAR (18–20) and metformin (18, 21) promote hepatic fat utilization and suppress lipogenic signaling. A major complication in determining the necessity of AMPK for the effects of glucagon, adiponectin, AICAR, and biguanides on hepatic metabolism is that they increase levels of nucleotide monophosphate (NMP) (6–10), which has multiple sites of action. To fully understand the mechanism of action of these hormones and pharmaceutical agents, it is necessary to distinguish the consequences of an increase in the NMP pool from the activation of AMPK on hepatic metabolism.

In the present studies, we tested the extent to which metabolic effects of increased hepatic NMP were dependent on AMPK. These experiments were carried out using an AICAR-euglycemic clamp in mice with a liver-specific removal of AMPK. The results demonstrate in vivo that an increase in hepatic NMP suppresses glucose production by a mechanism that is independent of hepatic AMPK. This finding challenges the paradigm that hepatic AMPK is required for acute gluco-regulation by AICAR. However, these studies support the hypothesis that AMPK maintains hepatic adenylate energy balance in the liver during AICAR administration by regulating mitochondrial function.

**EXPERIMENTAL PROCEDURES**

**Animal Models**—All procedures were approved by Vanderbilt University Animal Care and Use Committee. To generate a liver-specific AMPK knock-out mouse, albumin-cre+ mice were crossed with mice containing floxed AMPKα1 and α2 subunits on a C57BL/6 background. Genotyping and Western blots were performed to confirm liver-specific deletion of AMPK, defined as α1α2lox/lox + Albcre or wild type, α1α2lox/lox.

Mice were maintained on a 12:12 h light/dark cycle in a temperature- and humidity-controlled environment and given a chow diet (5.5% fat by weight; 5001 Purina laboratory rodent diet) with free access to water. On the day of the study, unrestrained 14–15-week-old male mice were fasted 5 h prior to clamp or sacrifice.

**Surgical Procedures and Body Composition**—All clamps were performed in chronically catheterized mice as previously described (22). Briefly, right jugular vein and left common carotid artery catheters were surgically implanted 5–7 days prior to study. The mice were individually housed postsurgery; only mice within 10% of their presurgical weight were studied. An uncatheterized cohort of 14-week-old male α1α2lox/lox and α1α2lox/lox + Albcre mice were used to determine body composition using an mq10 nuclear resonance analyzer (Bruker Optics).

**AICAR-Euglycemic and Saline Clamp**—On the day of study, the mice were placed in bedded containers without food and water between 07:00 and 08:00 for a 5-h fast (t = −300 to 0 min). Infusion lines were connected to the indwelling catheters 90 min prior to infusions to minimize stress. AICAR (Toronto Research Chemicals) or saline clamps were performed similar to previously described insulin clamps (23) with minor modifications. At t = −90 min, a primed continuous infusion of [3-3H]glucose was administered to determine 5-h fasting and clamp glucose kinetics. Samples were taken at t = −15 and −5 min to determine basal blood and plasma parameters followed by the start of a continuous infusion of donor erythrocytes to prevent a fall in hematocrit during the clamp. At t = 0 min, AICAR or saline was delivered as a primed (40 mg.kg−1), continuous infusion (8 mg.kg−1·min−1) followed by a variable infusion of 50% dextrose to clamp blood glucose levels at 110 mg.dl−1. The AICAR infusion rate was selected to parallel the conditions of earlier clamps in rodents (24, 25), which afforded a more robust basis for comparing AMPK-dependent and -independent changes in metabolism. [3-3H]Glucose was mixed with the glucose infusate to minimize fluctuations in specific activity during the clamp steady state. Arterial glucose was monitored from a 5-μl blood sample (AccuCheck Advantage; Roche Diagnostics) every 10 min, and the glucose infusion rate (GIR) was adjusted to account for deviations from 110 mg.dl−1. Glucose kinetics and plasma metabolites were determined from arterial samples taken during the clamp steady state (t = 80–120 min). Blood samples were collected in EDTA-coated tubes and centrifuged, and the plasma layer was stored at −20 °C for subsequent analysis.

**Plasma and Tissue Analyses**—Immunoreactive insulin was measured using a double-antibody method (26). Plasma [3-3H]glucose radioactivity was determined by scintillation counting (22), and rates of endogenous glucose production (EndoRa) and disappearance (Rd) were calculated using modified Steele’s non-steady-state equations (27). Lactate was monitored from a 5-μl blood sample (AccuCheck Advantage; Roche Diagnostics) every 10 min, and the glucose infusion rate (GIR) was adjusted to account for deviations from 110 mg.dl−1. Glucose kinetics and plasma metabolites were determined from arterial samples taken during the clamp steady state (t = 80–120 min). Blood samples were collected in EDTA-coated tubes and centrifuged, and the plasma layer was stored at −20°C for subsequent analysis.

At the end of the clamp, the mice were euthanized through cervical dislocation, and liver tissue was excised and freeze-clamped (<20 s) to prevent hypoxia driven changes in nucleotides. Hepatic adenine nucleotides were measured via HPLC through Vanderbilt’s Hormone Assay and Analytical Services Core. ~60 mg of frozen liver tissue was rapidly homogenized in 0.6 ml of ice-cold 0.4 M HClO4 containing 0.5 mM EGTA. Samples sat on ice for another 3 min and were centrifuged at 3200 g for subsequent analysis.

For glycogen measurements, the liver was homogenized in 0.03 M HCl (0.1 mg of tissue/μl) and incubated at 80 °C for 10 min. A volume of the digest was applied to chromatography strips, dried, washed three times in 70% EtOH, and briefly...
AMPK-related Effects of NMP on Hepatic Metabolism

......

RESULTS

Body Composition and 5-h Fasted Metabolites—A cohort of 14-week-old α1α2lox/lox and α1α2lox/lox + Albcre mice were assayed to determine whether the absence of hepatic AMPK impacted whole body weight and composition. There were no apparent differences in body composition (Table 1). 5-h fasted arterial glucose, plasma insulin, free fatty acids, lactate, and triglycerides (TGs) were not different between α1α2lox/lox and α1α2lox/lox + Albcre (Table 1).

AICAR-mediated Inhibition of Glucose Production Is Independent of Acute AMPK Activation—In vivo and in vitro delivery of AICAR to hepatocytes inhibits glucose production (8, 24). To test whether AICAR requires AMPK for the inhibition of endogenous glucose production (EndoRa), AICAR was continuously infused at 8 mg/kg·min−1, and blood glucose was clamped at ~110 mg/dl−1. During the experimental period, the GIR required to maintain euglycemia (Fig. 1A) was similar between genotypes in both saline and AICAR clamps (Fig. 1B); however, the sustained elevation in GIR was significantly higher with the infusion of AICAR than saline controls. EndoRa and glucose disappearance (Rd) were indistinguishable between genotypes prior to and during the AICAR or saline clamp (Fig. 1, C and D). AICAR inhibited EndoRa equivalently in α1α2lox/lox and α1α2lox/lox + Albcre mice (0.8 ± 1.4 and 1.1 ± 2.4 mg/kg·min−1). Likewise, AICAR induced an equal increment in Rd in α1α2lox/lox and α1α2lox/lox + Albcre mice (31.0 ± 1.2 and 32.8 ± 1.5 mg/kg·min−1). Plasma insulin levels were indistinguishable between the saline and AICAR clamp groups (Table 2). The data show that the inhibition of EndoRa by AICAR (Fig. 1, C and D) is disassociated from its capacity to activate AMPK (Fig. 2A) in vivo. AMPK deletion also provoked a reduction in liver glycogen (Table 2), which did not impact AICAR-mediated inhibition of EndoRa.

The 2-h AICAR infusion blunted plasma free fatty acid and plasma TG concentrations in α1α2lox/lox and α1α2lox/lox + Albcre mice (Table 2). Indeed, AICAR was so potent at clearing free fatty acids that circulating levels were undetectable in α1α2lox/lox mice (Table 2). AICAR elicited 6.6 ± 0.6- and 5.2 ± 0.5-fold increases in plasma lactate over saline in α1α2lox/lox and α1α2lox/lox + Albcre mice, respectively. The elevation in plasma lactate, however, was partially attenuated in α1α2lox/lox + Albcre mice (Table 2).

**Results**

Body composition and 5-h fasted metabolites—A cohort of 14-week-old α1α2lox/lox and α1α2lox/lox + Albcre mice were assayed to determine whether the absence of hepatic AMPK impacted whole body weight and composition. There were no apparent differences in body composition (Table 1). 5-h fasted arterial glucose, plasma insulin, free fatty acids, lactate, and triglycerides (TGs) were not different between α1α2lox/lox and α1α2lox/lox + Albcre (Table 1).

AICAR-mediated inhibition of glucose production is independent of acute AMPK activation—In vivo and in vitro delivery of AICAR to hepatocytes inhibits glucose production (8, 24). To test whether AICAR requires AMPK for the inhibition of endogenous glucose production (EndoRa), AICAR was continuously infused at 8 mg/kg·min−1, and blood glucose was clamped at ~110 mg/dl−1. During the experimental period, the GIR required to maintain euglycemia (Fig. 1A) was similar between genotypes in both saline and AICAR clamps (Fig. 1B); however, the sustained elevation in GIR was significantly higher with the infusion of AICAR than saline controls. EndoRa and glucose disappearance (Rd) were indistinguishable between genotypes prior to and during the AICAR or saline clamp (Fig. 1, C and D). AICAR inhibited EndoRa equivalently in α1α2lox/lox and α1α2lox/lox + Albcre mice (0.8 ± 1.4 and 1.1 ± 2.4 mg/kg·min−1). Likewise, AICAR induced an equal increment in Rd in α1α2lox/lox and α1α2lox/lox + Albcre mice (31.0 ± 1.2 and 32.8 ± 1.5 mg/kg·min−1). Plasma insulin levels were indistinguishable between the saline and AICAR clamp groups (Table 2). The data show that the inhibition of EndoRa by AICAR (Fig. 1, C and D) is disassociated from its capacity to activate AMPK (Fig. 2A) in vivo. AMPK deletion also provoked a reduction in liver glycogen (Table 2), which did not impact AICAR-mediated inhibition of EndoRa.

The 2-h AICAR infusion blunted plasma free fatty acid and plasma TG concentrations in α1α2lox/lox and α1α2lox/lox + Albcre mice (Table 2). Indeed, AICAR was so potent at clearing free fatty acids that circulating levels were undetectable in α1α2lox/lox mice (Table 2). AICAR elicited 6.6 ± 0.6- and 5.2 ± 0.5-fold increases in plasma lactate over saline in α1α2lox/lox and α1α2lox/lox + Albcre mice, respectively. The elevation in plasma lactate, however, was partially attenuated in α1α2lox/lox + Albcre mice (Table 2).
AMPK-related Effects of NMP on Hepatic Metabolism

AMPK activation during energy stress is implicated in fat utilization in the liver (15). Liver TG levels in \(\alpha1\alpha2^{lox/lox}\) and \(\alpha1\alpha2^{lox/lox} + \text{Albcre}\) mice at the end of the saline infusion were not statistically different (24.6 ± 0.8 and 29.1 ± 2.0 mg/g of liver) (Table 2). The AICAR infusion in \(\alpha1\alpha2^{lox/lox}\) mice reduced hepatic TG concentrations compared with saline controls (19.7 ± 1.5 versus 24.6 ± 0.8 mg/g of liver, \(p = 0.08\)). \(\alpha1\alpha2^{lox/lox} + \text{Albcre}\) mice did not experience the same AICAR-mediated reduction as hepatic TG concentrations were significantly higher than \(\alpha1\alpha2^{lox/lox}\) mice at the end of the clamp (Fig. 2B). Indeed, AICAR can promote carnitine palmitoyltransferase-1 activity independent of changes in malonyl-CoA (30). Thus, AICAR facilitates a decrease in liver TGs via hepatic AMPK.

FIGURE 1. Acute inhibition of glucose production by AICAR is independent of hepatic AMPK. A and B, arterial glucose (A) and GIR (B) during AICAR and saline clamps in \(\alpha1\alpha2^{lox/lox}\) and \(\alpha1\alpha2^{lox/lox} + \text{Albcre}\) mice. Mice were fasted 5 h prior to the primed (40 mg/kg \(\cdot\)min \(^{-1}\)) infusion of AICAR (8 mg/kg \(\cdot\)min \(^{-1}\)) or saline. Blood glucose was clamped at 110 mg/dl, and the time course is displayed to demonstrate experimental quality. 50% dextrose was infused to maintain euglycemia during the steady state of the clamp (\(t = 80–120\) min). C and D, endogenous glucose production (EndoRa) and disappearance (Rd) during the basal period (5-h fasted) (C) and steady state of the AICAR clamp (D) in \(\alpha1\alpha2^{lox/lox}\) and \(\alpha1\alpha2^{lox/lox} + \text{Albcre}\) mice. GIR means from the experimental period were analyzed for significance. The data are expressed as means ± S.E., \(n = 5–7\) in each group. *, \(p \leq 0.05\) versus saline.

AMPK Counts a Decrease in Hepatic Adenylate Energy Charge during an Acute AICAR Challenge in Vivo—The primed AICAR infusion resulted in comparable hepatic ZMP levels in the two genotypes (Fig. 3C). The conversion of AICAR to ZMP utilizes ATP (31), and ZMP has been demonstrated to inhibit complex I respiration in isolated mitochondria (16). Adenylate kinase maintains the equilibrium between ATP, ADP, and AMP; physiological and pharmacological perturbations in metabolism can alter this balance (6, 8–11). Thus, hepatic ATP, AMP, and ADP were measured to investigate how an acute AICAR infusion perturbs hepatic adenylate energy balance in a euglycemic, in vivo setting. Liver ATP levels were comparable in \( \alpha_1\alpha_2^{\text{lox/lox}} \) and \( \alpha_1\alpha_2^{\text{lox/lox}} + \text{Albcre} \) mice (1.7 ± 0.12 versus 1.5 ± 0.09 \( \mu \text{mol g}^{-1} \)) that received the saline infusion (Fig. 3A). The AMP/ATP ratio and EC were similar to previous measurements taken under postabsorptive conditions (11). The AICAR infusion perturbs hepatic adenylate energy balance in vivo. These data are consistent with the effects of metformin and AICAR in vitro (8).

Mitochondria from \( \alpha_1\alpha_2^{\text{lox/lox}} + \text{Albcre} \) Mice Display Impairments in Mitochondrial Function—Livers from \( \alpha_1\alpha_2^{\text{lox/lox}} + \text{Albcre} \) mice demonstrate an impaired capacity to utilize fat and maintain ATP levels during an acute AICAR challenge. Given the importance of oxidative phosphorylation in these interrelated processes, we hypothesized that hepatic mitochondria from \( \alpha_1\alpha_2^{\text{lox/lox}} + \text{Albcre} \) mice would demonstrate impairments in integrative oxidative phosphorylation function compared with WT littermates. Polarographic oxygen consumption measurements were performed on mitochondria isolated from the livers of \( \alpha_1\alpha_2^{\text{lox/lox}} + \text{Albcre} \) mice. The absence of hepatic AMPK had no effect on glutamate-, malate-, and pyruvate-supported basal oxygen consumption (state 2) (Fig. 4A). ADP-stimulated oxygen consumption (state 3), however, was attenuated in \( \alpha_1\alpha_2^{\text{lox/lox}} + \text{Albcre} \) mouse (Fig. 4A). The addition of the ATP-synthase inhibitor oligomycin demonstrated that nonphosphorylating oxygen consumption was no different between \( \alpha_1\alpha_2^{\text{lox/lox}} + \text{Albcre} \) mice (Fig. 4A) but equaled \( \alpha_1\alpha_2^{\text{lox/lox}} + \text{Albcre} \) when normalized to state 3 and
AMPK-related Effects of NMP on Hepatic Metabolism

A. Oxygen Flux

B. RCR

C. Mitochondrial Complex Expression

FIGURE 4. Oxygen flux data from mitochondria isolated from the livers of α1α2lox/lox and α1α2lox/lox + Albcre mice. A, mitochondrial respiration was measured in the presence of the OXPHOS substrates glutamate, malate, and pyruvate (State 2) in the presence of saturating ADP (State 3), oligomycin (Leak), and FCCP (electron transport system, ETS). B, the respiratory control ratio (RCR) is defined as the ratio of state 3 to state 2 oxygen consumption. C, mitochondrial complex expression in isolated mitochondria from the livers of α1α2lox/lox and α1α2lox/lox + Albcre mice was measured through Western blotting (normalized to VDAC1). The representative images are lanes obtained from different parts of the same immunoblot. The data are expressed as means ± S.E., n = 5–6 in each group. †, p < 0.05 versus α1α2lox/lox; $, p > 0.05 versus α1α2lox/lox, absolute rates are significantly different but not when normalized to state 3 and leak respiration.

Leak respiration.3 Impaired state 3 respiration in α1α2lox/lox + Albcre mice led to a reduction in the respiratory control ratio—an index of mitochondrial efficiency—compared with α1α2lox/lox controls (Fig. 4B). These data indicate that hepatic AMPK supports efficient coupling of ADP phosphorylation and oxygen consumption. In addition, the removal of hepatic AMPK was sufficient to reduce the expression of mitochondrial complexes II and III (Fig. 4C). These results are consistent with the demonstration that hepatic AMPK activity is protective against a greater reduction in EC and elevation in the AMP/ATP ratio in response to AICAR.

DISCUSSION

Compounds (endogenous and pharmaceutical) and conditions that increase hepatic AMPK activity have been demonstrated to mitigate hepatic processes central to the etiology of diabetes and obesity (6–8, 18–21, 32–38). Here we use genetic tools to distinguish between the AMPK-dependent and -independent effects of AICAR in vivo. Recent evidence challenges the role of AMPK as an indispensable arbiter for the anti-glycemic effects that are mediated by hepatic AMPK and those that are not. This was accomplished by increasing the NMP concentration in the presence of a fixed glucose concentration using an AICAR-euglycemic clamp technique in the presence and absence of hepatic AMPK in vivo.

AMPK activation is broadly implicated in the transcriptional control of mediators of gluconeogenesis (17, 39–44). Cre-mediated removal of the AMPKα2 catalytic subunit from the liver results in substantial increases in fasting glucose and insulin (45). It has also been demonstrated that the overexpression of constitutively active AMPKα2 reduces fasting glucose with a concomitant attenuation of phosphoenolpyruvate carboxykinase and glucose-6-phosphatase gene expression (17). Moreover, AICAR attenuates the gene expression of phosphoenolpyruvate carboxykinase and glucose-6-phosphatase; this effect has been attributed to AMPK activation (40, 42, 44), but the requirement for this enzyme in acute control has recently been strongly contested in primary hepatocytes and metabolic tests in vivo (8). We demonstrate that the genetic removal of both AMPKα1 and α2 catalytic subunits from the liver has no impact on rates of endogenous glucose production or disappearance in the conscious, 5-h fasted mouse. During euglycemia, liver AMPK is neither required for the AICAR-mediated inhibition of EndoRa nor its stimulation of glucose disappearance. These data impart two important results regarding the role of AMPK in the acute glucoregulation: the genetic deletion of AMPK from the liver (a) does not affect 5-h fasting glucose kinetics and (b) is unnecessary for the AICAR-mediated suppression of EndoRa in the short-fasted mouse.

Although these studies highlight the power of AICAR to inhibit glucose production in vivo, the results do not discount the possibility that hepatic AMPK participates in the regulation

AMPK-related Effects of NMP on Hepatic Metabolism

of glucose flux under other conditions. The experiments were designed to study glucose flux in the short-fasted, postprandial mouse to limit the effects of fast duration on hepatic nucleotides and AMPK signaling. Applying physiological stressors that reduce energy state (i.e., acute, high intensity exercise) may uncover a role for hepatic AMPK in glucose regulation that is not evident when energy state is reduced using AICAR. These and other recent studies (6, 8, 10) emphasize the need to demarcate the in vivo effects of AMPK in physiology from pharmacology.

Recent literature on glycemic regulation by glucagon (10) and biguanides (6, 8) has reinvigorated the conversation surrounding AMP and energy charge as regulatory variables (46, 47). Glucagon-mediated flux through phosphoenolpyruvate carboxykinase appears to generate an autoregulatory feedback loop limiting the amount of ATP disposed to gluconeogenesis (10). These studies demonstrate that the unique plasticity of liver EC has an important function in response to a normal elevation in endocrine action. Indeed, glucagon provokes distinct changes in liver function that correspond to a relative decrease in available ATP (10), despite the stimulation of fat oxidation and suppression of triglyceride synthesis (48).

A therapeutic advantage of AMPK-activators like AICAR and biguanides is that they are not dependent on cataplerotic flux for an increase in the AMP/ATP ratio. Rather, metformin has been shown to inhibit mitochondrial complex I activity (49, 50), depress energy charge, and activate AMPK (8). AMP has the capacity to inhibit fructose 1,6-bisphosphatase (51) and adenylyl cyclase (6). ZMP, the AMP mimetic generated from 50), depress energy charge, and activate AMPK (8). AMP has been shown to inhibit mitochondrial complex I activity (49, 50), compete for the provision of reducing equivalents.During AICAR administration. No differences in adenine nucleotides, EC, or AMP/ATP were observed in short-fasted, euglycemic alox/lox and alox/lox + Albcre mice receiving the saline infusion. Thus, defects in substrate utilization and mitochondrial function in alox/lox + Albcre mice only affect liver energy state when linked with elevated metabolic stress.

Similar to the effects of metformin, ZMP interferes with complex I and impairs state 3 respiration (16). AMPK may promote AMPK-dependent and -independent fat transport into the mitochondria yet impede cofactor oxidation. As a result, liver energy charge may decline despite a relative abundance of substrate, NADH, and FADH2. A similar hypothesis has been proposed for the actions of metformin (54).

The deleterious effect of AICAR on EC may be compounded by the inhibition of hepatic glucose uptake. AICAR delivery into the portal vein renders the liver insensitive to net hepatic glucose uptake, even during hyperglycemia and hyperinsulinemia (52). In vitro work confirms that AICAR reduces glucokinase translocation and glycolysis in hepatocytes (55), in AMPK-dependent (56) and -independent (57) conditions. Our AICAR delivery rate was selected to permit a reasonable physiological comparison between our results and earlier AICAR-euglycemic clamps in rodents (24, 25). The resulting dose was sufficient to perturb hepatic adenylyl energy balance, and we expect that the depletion of ATP could contribute to an inhibition of liver glycolysis (56, 57). AICAR also elevates plasma lactate in vivo (24, 37), which may result from increased production from muscle (58) and impaired uptake in the liver (38). Because AICAR induces an equal increment in glucose disappearance, it is reasonable to assume that muscle lactate production is unaffected by liver AMPK knock-out. The attenuated elevation in plasma lactate in alox/lox + Albcre mice may instead reflect a switch in substrate uptake and utilization in the liver during AICAR administration.

The metabolic challenge induced by AICAR inhibits both glucose flux in and out of the liver, effectively generating a condition in which the liver may become more reliant on fat oxidation. Ample molecular and physiological evidence connects AMPK activation with fat utilization in the liver. AICAR reduces hepatic TGs under various conditions in rodents (18–20) and increases fatty acid oxidation in hepatocytes (21, 30, 59). Knock-out of the AMPKα2 subunit in the liver (45) results in increased circulating fatty acids, TGs, and a decrease in β-hydroxybutyrate, whereas the short term overexpression of a constitutively active form of AMPKα2 reduces plasma TGs and increases β-hydroxybutyrate (17). Together, these results suggest that AMPK mediates fatty acid uptake and oxidation. Our data demonstrate that the acute effect of AICAR on hepatic TG utilization requires liver AMPK. pACC579 is undetectable in alox/lox + Albcre mice and, thus, higher in AICAR-treated alox/lox mice (Fig. 2B), implicating increased carnitine palmitoyltransferase-1 activity as a potential mechanism for elevated fat oxidation in the liver. However, pACC579 was not different between alox/lox saline and alox/lox AICAR. It is plausible that increased NMP drives fatty acid flux away from de novo lipogenesis and through carnitine palmitoyltrans-
AMPK-related Effects of NMP on Hepatic Metabolism

AMPK has been shown to regulate mediators of TG and cholesterol synthesis (14, 60–62). At the end of the AICAR infusion, higher liver TGs in α1α2lox/lox + Albcre mice could conceivably result from an impaired inhibition of TG synthesis or esterification. If this were the case, one might expect circulating TGs to follow a similar trend, yet circulating TGs were equivalent in α1α2lox/lox and α1α2lox/lox + Albcre mice. Evidence from these studies point to impairments in fat utilization as a source of elevated TGs in the livers of α1α2lox/lox + Albcre mice following AICAR administration.

Collectively, the data provide in vivo support for the energy sensor paradigm (63). AMPK acts as a sensor and safeguard of the hepatic adenylate energy pool during an acute challenge to the energy status of the liver. The absolute amounts of ATP, ADP, and AMP in the liver are dictated by changes in synthesis and breakdown, with adenylate kinase coordinating their relative balance. Genetic deletion of AMPK exacerbates the AICAR-mediated disturbance of the adenylate pool and a larger reduction in available ATP. The evidence suggests that AMPK works to promote fat utilization and mitochondrial function during a pharmacological increase in ATP consumption, as liver AMPK knock-out leaves liver TGs elevated. These data prove that AMPK is not required for the acute inhibition of endogenous glucose production during elevations in AMP, the AMP/ATP ratio, or ZMP in vivo. This and other recent research (6–8) have important implications for therapeutics designed to target the pathogenesis of diabetes and metabolic diseases.

Acknowledgments—We thank Susan Hajizadeh in the hormone assay and analytical services core at Vanderbilt for measuring plasma insulin. We also thank Jeffrey S. Bonner for careful review of the manuscript.
