Safety issues of endobronchial intubation for one-lung ventilation in video-assisted thoracoscopic surgery in neonates: Can we extubate on the table?

Sir,

Advances in pediatric anesthesia have made it possible for complex surgical procedures such as video-assisted thoracoscopic surgery (VATS)\(^1\) in neonates. However, VATS in neonates remains a challenge because of a different anatomy and challenging physiology compared to older children.\(^2\) Different techniques described for one-lung ventilation (OLV) in pediatric patients may sound assuring, but it is practically difficult and challenging to execute. Moreover, techniques describe for older children cannot be extrapolated to neonatal practice.

We report our experience of anesthetic management of a term neonate (20 days) weighing 3200 g with an isolated left diaphragm eventration for VATS repair. The child had a saturation of 97% in room air. After intravenous induction, right main stem bronchus (MSB) was intubated with a 3.5 mm ID endotracheal tube (ETT). OLV was confirmed by auscultation of the chest as a compatible fiberoptic bronchoscope was not available. Right radial artery was cannulated and the neonate was positioned. Thoracic cavity was insufflated with CO\(_2\) to attain a pressure of 4 mmHg. Pressure control ventilation was used with a set pressure of 15 mmHg; respiratory rate = 30/min; positive end-expiratory pressure (PEEP) = 4. During the surgery, there was a continuous rise in the end-tidal CO\(_2\) (ETCO\(_2\)) level, so the set pressure was gradually increased to 30 mmHg and the intrathoracic pressure decreased to 2 mmHg to achieve the required minute ventilation. Intermittent manual ventilation was required with 100% oxygen to wash out the retained CO\(_2\). A blood gas sample analysis of PaCO\(_2\) corroborated with the high ETCO\(_2\). The operation lasted for 70 min, and the ETT was withdrawn by 1.5 cm for both-lung ventilation toward the end of surgery. The PaCO\(_2\) at the end of surgery was significantly raised with respiratory acidosis, and hence, the child was shifted to neonatal intensive care unit for mechanical ventilation in the postoperative period. Ventilator support was gradually weaned off, and trachea was extubated 5 h later, and the perioperative outcome was uneventful.

OLV, though preferable, is not mandatory for all VATS procedures.\(^2\) Neonates are more prone to desaturation during OLV due to increase oxygen consumption, more V/Q mismatch in lateral decubitus position,\(^2-4\) and decrease functional residual capacity.\(^2,4\) The main concerns are hypoxemia, hypercarbia, hypothermia, and hemodynamic instability during CO\(_2\) insufflation. The options available for OLV in neonates are limited. Endobronchial intubation and blocker\(^4\) can be used for OLV in newborn.

The safety margin of MSB intubation for OLV is low due to tracheobronchial injury, obstruction of upper lobe bronchus, inability to provide endotracheal suction or PEEP to nondependent lung,\(^4\) and minimal peri-tube leakage of air can underestimate the ETCO\(_2\). There is no established gold standard for OLV and ventilation strategies during VATS in neonates, and there are limited data on the safety concern for anesthetic management of VATS in neonates.
Vigilant monitoring during OLV in neonates is required as ETCO$_2$ can underestimate hypercarbia. Blood gas analysis can guide us for postoperative ventilator requirement apart from intraoperative hemodynamic monitoring. Whether to extubate on the table has to be decided as per the perioperative events and has to be individualized.

Sir,

Intracardiac thrombus (ICT) is a multifactorial condition that can occur after major vascular surgeries. ICT is uncommon after liver transplantation (LT), and mortality is high. Activation of coagulation system, stasis-induced inferior vena cava and portal vein clamping, massive blood transfusion, and venovenous bypass predispose to thrombus formation after reperfusion. [1]

In the current study, we present a patient who underwent cardiac surgery because of right atrium thrombus after LT. [2] A 49-year-old, 65 kg female patient admitted to our hospital with dyspnea, which was received a live donor. A thrombus was detected in the right atrium, right main pulmonary artery, left main pulmonary artery bifurcation, and the distal of vena cava inferior starting from the main iliac vein [Figure 1a]. Transthoracic echocardiography after LT that is done 6 months ago was normal. The patient was taken to the operating room. Anesthesia induction was included. Cardiopulmonary bypass time was 135 min and thrombus in size 2 cm × 1.5 cm was removed [Figure 1b]. No complications were observed during the operation. The patient was taken to the intensive care unit and died due to deterioration of overall situation 4 days later.

Anesthetic management of a patient who has ICT during or after LT is extremely important. ICT can lead to many complications that can cause to intraoperative death. Peiris et al. [2] have reported that venous thrombosis, atrial fibrillation, and transjugular intrahepatic portosystemic shunt for portal hypertension (TIPS) are responsible for ICT. Intracardiac thrombosis after liver transplantation: Can it be detected before surgery?
