We propose a physical system allowing one to experimentally observe the distribution of the complex zeros of a random polynomial. We consider a degenerate, rotating, quasi-ideal atomic Bose gas prepared in the lowest Landau level. Thermal fluctuations provide the randomness of the bosonic field and of the locations of the vortex cores. These vortices can be mapped to zeros of random polynomials, and observed in the density profile of the gas.

PACS numbers: 03.75.Lm, 05.40.-a

An important field of study in theoretical statistical physics concerns the properties of the roots of random polynomials [1, 2]. Of particular interest is the so-called Weyl polynomial for the complex variable ζ:

\[ P(ζ) = \sum_{m=0}^{m_{\text{max}}} a_m \frac{ζ^m}{\sqrt{m!}} \]  

where the \(a_m\)'s are independent random complex numbers with the same Gaussian probability distribution. The roots of \(P\) in the complex plane can be mapped to a two-dimensional (2D) gas of particles with repulsive interactions. They are spatially antibunched, and have a uniform mean density in the large \(m_{\text{max}}\) limit [2].

Although the statistical properties of the roots of the Weyl polynomial have been well studied theoretically, no physical system has allowed yet to observe them directly. The goal of this Letter is to show that a 2D rotating ideal Bose gas is a well suited system for this observation. The positions of the vortices appearing in the gas can be mapped to the zeroes of the random polynomial describing the atomic state. More precisely, the gas is harmonically trapped and it rotates at a frequency close to the trapping frequency so that it is ‘frozen’ in the lowest Landau level (LLL) [4, 5]. Its finite temperature \(T\) ensures that several vortices are present in the region where atomic density is significant, and thermal fluctuations provide the randomness of the vortex locations in different realizations of the experiment. Such an experiment is not unrealistic: a 2D atomic Bose gas in the LLL has recently been produced [6], and the use of a Fano-Feshbach scattering resonance allows to nearly cancel the interactions between ultra-cold atoms [7]. This regime of an ideal gas with large thermal fluctuations dramatically differs from the well studied case of a rotating and interacting Bose-Einstein condensate in the LLL at \(T = 0\), where the vortices are known to form an Abrikosov lattice [4, 8, 9].

The ideal gas in our model is confined in a harmonic trap, with oscillation frequency \(ω\) in the \(xy\) plane and \(ω_z\) along \(z\). The confinement along \(z\) is assumed to be strong, \(k_B T \ll \hbar ω_z\), so that the \(z\) degree of freedom is frozen and the gas is kinematically 2D. We also assume that some angular momentum has been transferred to the gas by a stirring procedure [8], so that thermal equilibrium is reached in a frame rotating at frequency \(Ω\) around \(z\). \(Ω\) is chosen close to the trapping frequency \(ω\):

\[ ω - Ω \ll ω , \]  

which is experimentally realistic since the value \((ω - Ω)/ω = 0.01\) has already been achieved [6]. We also assume that the gas is cooled to a low enough temperature, \(k_B T \ll 2\hbar ω\), so that the relevant single particle states are linear combinations of the LLL eigenmodes: [4, 8]

\[ φ_m(x,y) = \frac{ζ^m}{\sqrt{πm!}} e^{-ζ^2}/2 , \quad ζ = x + iy . \]  

Here \(a_{ho} = \sqrt{\hbar/Mω}\) (where \(M\) is the atomic mass) is taken as the unit of length. The mode energy \(ε_m = \hbar ω\) depends on a single quantum number \(m \geq 0\) so that thermodynamically the gas is effectively 1D.

The relevant quantity in our study is the density of vortices, which we will define in relation with the complex classical field \(ψ(r)\) describing the state of the gas. This classical field represents not only the condensate (atoms in the vortex-free mode \(ψ_0\)) but also all superimposed thermal fluctuations. We obtain \(ψ\) using the expression for the many-body density operator \(σ\) of the ideal gas in thermal equilibrium in the grand canonical ensemble [9]:

\[ σ = \int dψ P(\{ψ\}) |\text{coh} : ψ⟩⟨\text{coh} : ψ| . \]  

In this expression \(σ\) is a statistical mixture of Glauber coherent states \(|\text{coh} : ψ⟩\), with positive weights \(P(\{ψ\})\) (the so-called Glauber P distribution) given by the Gaussian functional specified below. A given realization of the experiment can then be viewed as a random draw of the atomic field state \(ψ\), with the probability law \(P(\{ψ\})\).

The stochastic nature of \(ψ\) is simple to characterize by expanding it on the eigenmodes \(φ_m\):

\[ ψ(r) = \sum_{m \geq 0} a_m φ_m(r) . \]
The $a_m$'s are complex, statistically independent random numbers, with a Gaussian law:

$$P(\{\psi\}) \propto \prod_{m \geq 0} e^{-|a_m|^2/n_m}$$

(6)

where $n_m = [\exp(\beta(\epsilon_m - \mu)) - 1]^{-1}$ is the mean occupation number of mode $m$. Here $\beta = 1/k_B T$ and $\mu$ is the chemical potential. This provides a clear link with the random polynomial of Eq. (1) when several $n_m$ have similar values:

$$\psi(\mathbf{r}) = f(\zeta) e^{-\zeta^2/2} \sqrt{\pi} , \quad f(\zeta) = \sum_m a_m \zeta^m \sqrt{m!} .$$

(7)

When $f(\zeta)$ is factorized as $f(\zeta) \propto \prod_i (\zeta - \zeta_i)$, each root $\zeta_i$ corresponds to the location of a positively charged vortex in the field $\psi$. Since having a multiple root is a zero measure event, these vortices are of charge unity. Note that $\psi$ results from the interference of a large number of macroscopically populated field modes, reminiscent of the interference of independent condensates.

The statistics of the roots then do not coincide with the standard results of the literature, and we must perform a study of this specific model. To provide an intuitive understanding on how the roots of $f(\zeta)$ are distributed, we first show in figure 1 numerical results for a randomly generated field $\psi$. We take $k_B T = 500 \hbar(\omega - \Omega)$, which is compatible with the condition $k_B T \ll 2\hbar \omega$ for the experimentally realistic value $\Omega = 0.999 \omega$. On the first and second lines of figure 1 we show plots of $\ln(|\psi|^2)$ and $|\psi|^2$, respectively, for 3 values of $\mu$. In all cases, the root locations are clearly visible.

We now turn to an analytic study of the problem and we express the algebraic density of vortices $\rho_v(\mathbf{r})$ in terms of $\psi$ and its derivatives. A helpful simplification is to eliminate the Gaussian factor in Eq. (7), which does not change the vortex locations, and use $f(\zeta)$ rather than $\psi(\mathbf{r})$ as a random field. Using $\partial_\zeta f(\zeta) = i\partial_\zeta f(\zeta) = if'(\zeta)$, we obtain:

$$\rho_v(\mathbf{r}) = |f'|^2 \delta(\zeta - f'(\zeta))$$

(8)

making it obvious that all vortices have a positive charge in the LLL.

The expectation value of $\rho_v$ gives the average vortex density $\bar{\rho}_v$, the correlation function $\langle \rho_v(\mathbf{r} - \mathbf{u}/2)\rho_v(\mathbf{r} + \mathbf{u}/2) \rangle$ gives the vortex pair distribution function $\rho_2$, etc. Using properties of Gaussian statistics, these quantities can be expressed in terms of expectation values of products of two fields, such as $f, f^*$, or their derivatives with respect to $\zeta$.

The general expression for the pair distribution function $\rho_2$ is rather involved, and we give it only for small relative distances $u$. It vanishes quadratically with $u$, showing the effective repulsion between the vortices:

$$\rho_2(\mathbf{r} - \mathbf{u}/2, \mathbf{r} + \mathbf{u}/2) = C(\mathbf{r}) \frac{u^2}{8\pi^2} + O(u^3) ,$$

(10)

where $C$ is a function of $f, f^*$, and their first and second derivatives.
We find that the experimentally relevant situation $\Omega < \omega$ leads to results similar to those of the standard random polynomial theory (formally corresponding to $\Omega = \omega$) in the vicinity of the trap center when the two following conditions are fulfilled. Firstly, many eigenmodes have to be thermally populated:

$$k_B T \gg \hbar (\omega - \Omega).$$

(11)

Secondly, the low energy modes must have comparable populations, imposing a negative chemical potential $|\mu| \gg \hbar (\omega - \Omega)$. This is the situation depicted in the left column of figure 1 and in figure 2.

If $|\mu|$ is reduced for a fixed $T$, the mean number of atoms increases and an imbalance appears among the populations of the low energy modes. The vortex density is then depleted near the trap center, as it can be seen in the middle and right columns of figure 1 and in figure 2.c. Eventually, for $|\mu| < \hbar (\omega - \Omega)$, the total population of the modes $m \neq 0$ saturates and a condensate forms in the mode $m = 0$. This condensate has no vortex and it expels the thermal vortices, which accumulate in a corona with a density locally exceeding $1/\pi$ (figure 2c).

The situation at the onset of condensation is relevant experimentally since it is tempting to increase the number of atoms in order to improve the experimental signal. To extend quantitatively our analysis to this regime, we must replace the grand canonical ensemble, which presents non physical, large fluctuations of the total particle number when a condensate is present, by the canonical ensemble. We then adapt our definition of the vortex distribution by projecting Eq. 1 on a subspace with a fixed total number of particles $N$, resulting in the following probability distribution of the field $\psi$:

$$P_c(\{\psi\}) \propto P(\{\psi\}) ||\psi||^{2N} / N! e^{-||\psi||^2}$$

(12)

where $||\psi||^2 = \int |\psi|^2$. The key change with respect to the grand canonical ensemble is that the probability distribution of the field is no longer Gaussian, showing that the proposed physical system opens a new class of problems. We evaluate numerically the vortex density using a generating function technique [14]. In the trap center, one can also construct an exact mapping to a solvable problem, the calculation of the canonical partition function and occupation numbers for a 1D ideal Bose gas in a harmonic trap [15]. This leads to the exact expression:

$$\bar{\rho}_v (r = 0) = \frac{1 - e^{-\beta \epsilon_1}}{\pi} \left[ \frac{1}{e^{\beta \epsilon_1} - 1} - n_1^c \right]$$

(13)

where $n_1^c$ is the mean number of particles in the first excited mode $m = 1$ (with $\epsilon_1 = \hbar (\omega - \Omega)$) in the canonical ensemble [14]. As shown in figure 2, the correct canonical result drops to a much smaller value than the incorrect grand canonical result in the trap center. In the large $N$ limit, one can show that $\bar{\rho}_v \sim N \exp[-(N + 1)\beta \epsilon_1]/\pi$ whereas the grand canonical prediction tends to zero only as $1/N$. Note that $\bar{\rho}_v (0)$ drops with $N$ similarly to the probability $\exp(-N\beta \epsilon_1)$ of having an empty condensate mode, which is a natural condition to have a vortex in $r = 0$.

How to observe the vortex density in practice? In current experiments with rotating interacting condensates, one measures the positions of the particles and the vortices appear as holes in the density profile [3]. This strategy can be used in regions of space where the mean density of particles $\rho$ greatly exceeds the density of vortices $\bar{\rho}_v$, here $\sim 1/\pi$. To each vortex embedded in such a high density region will correspond a clearly identifiable hole in the particle distribution. The maximal density of the non-condensed fraction of the gas is $\sim k_B T / (\pi \hbar (\omega - \Omega))$ close to the trap center, obtained for $|\mu| < \hbar (\omega - \Omega)$. Then $\rho \gg \bar{\rho}_v$ when Eq. 14 is satisfied. To indicate up to what distance from the trap center this condition holds, we have also plotted $\rho(r)/100$ in figure 2.

Conversely, do all the holes embedded in high density regions correspond to vortices? They may in principle correspond to a local minimum of $|\psi|^2$, where the field assumes a small but non zero value. Such ‘spurious’ local minima can in general form in a non-condensed ideal Bose gas, which is subject to large density fluctuations due to the thermal bunching effect of the bosons. However, we can show that this phenomenon is absent in the LLL. We Taylor-expand the field $\psi$ to second order in $u \equiv r - r_0$ around the location $r_0$ of a stationary point of
\(|\psi|^2\), assuming that \(\psi(\mathbf{r}_0) \neq 0\):

\[
|\psi(\mathbf{r})|^2 = |\psi(\mathbf{r}_0)|^2 \left[ 1 + \mathbf{u} \cdot \mathbf{M} \mathbf{u} + O(u^3) \right]
\]  

(14)

where the 2×2 matrix \(\mathbf{M}\) is real symmetric. One then finds that the trace of \(\mathbf{M}\) is

\[
\text{Tr}\ \mathbf{M} = \text{Re} \frac{\Delta \psi}{\psi} + \left| \nabla \psi \right|^2 = -2
\]

(15)

where we used Eq. (7) and \(\nabla|\psi|^2 = 0\) to get the last identity. Since its trace is \(< 0\), \(\mathbf{M}\) cannot be positive and \(|\psi|^2\) cannot have a local minimum at \(\mathbf{r}_0\).

We exemplify the above discussion by a Monte Carlo simulation of a real experiment for the parameters of figure 4. The results are shown on the last line of figure 4. Starting from the random fields \(\psi\) previously generated, we have produced these images by generating random positions of particles according to the distribution \(|\psi|^2\), and by mimicking the finite imaging resolution of a real experiment. Local minima of the density are visible, and can be checked on the images of the first and second lines to correspond to vortices. The visibility of the vortex pattern could be improved by increasing further the atom density. For a given ratio \(k_B T/\hbar \omega\), this can be achieved by rotating the gas even faster, so that \((\omega - \Omega)/\omega\) decreases.

In real life, there are interactions between the particles, characterized by the 3D s-wave scattering length \(a\). The interaction potential in the LLL is then modeled by the pseudo-potential \(g \delta^2(\mathbf{r}_1 - \mathbf{r}_2)\), with \(g = 2\sqrt{2\pi \hbar \omega a/\alpha_z}\), where \(\alpha_z = \sqrt{\hbar / M \omega z}\). We now derive a condition on \(a\) for the interactions to be negligible, in calculating to first order in \(g\) the effect of the interactions on the probability distribution of the vortices. Focusing on the quasi-homogeneous regime \(|\mu| \gg \hbar(\omega - \Omega)\), we set \(\Omega = \omega\). The unperturbed occupation numbers then all have the same value \(n_0\). The vortex density being uniform, even in presence of interactions, we consider the first order correction in \(g\) to the vortex pair distribution function \(\rho_2(\mathbf{u})\). Its expression can be simplified in the degenerate regime \(n_0 \gg 1\):

\[
\delta \rho_2(\mathbf{u}) / \rho_2^{(0)}(\mathbf{u}) \simeq -\frac{3\beta g n_0^2}{2} \int d^2 \mathbf{r} \left[ \frac{\rho_v(\mathbf{r})}{\rho_2^{(0)}(\mathbf{u})} \left| \psi(\mathbf{r}) \right|^4 - \left| \langle \psi(\mathbf{r}) \rangle \right|^4 \right],
\]

(16)

where the average is taken over the unperturbed distribution. The right hand side of Eq. (16) can be expressed analytically. It is maximal (in absolute value) in \(u = 0\):

\[
\lim_{u \to 0} \frac{\delta \rho_2(\mathbf{u})}{\rho_2^{(0)}(\mathbf{u})} = \frac{3\beta gn_0^2}{16\pi} \frac{g p}{|\mu|},
\]

(17)

whereas it drops as \(u^2 e^{-u^2/2}\) at large distances. Interactions will then play a negligible role in the vortex distribution if the mean field energy \(g p / |\mu|\) is much smaller than \(|\mu|\). For the realistic numbers \(k_B T = \hbar \omega / 2\), \(n_0 = 100\) and \(a_z = 1 \mu m\), the condition for negligible interactions is \(|a| < 0.2\) nm. The scattering length can indeed be tuned in practice to such a low value using a Fano-Feshbach resonance. This tuning should be done only during the last fraction of the experimental sequence, after having taken advantage of a larger value of \(a\) to reach thermal equilibrium in a reasonable time.

To summarize, the rotating quasi-ideal Bose gas is a promising system to implement in practice the concepts developed in the theory of random polynomials. It also raises novel questions such as the influence of the non-Gaussian statistics for the polynomial coefficients when a condensate is present. Finally we emphasize that our disordered vortex pattern appears in a non-superfluid system. An interesting future line of research is the transition to an ordered Abrikosov lattice when interactions are increased and the system becomes superfluid.

[13] We found \(C = B^2/A^3\), with \(A = (0,0,1) - |(1,0)|^2\) and \(B = (2,2,2) - |(2,1,1),(0,0,2) + c.c.| + |(2,1,1)|^2(0,0,0) + |(2,0,0)|^2(1,1,1)\), using the notation \((p,q) = (f^{(0)})^*(f^{(q)})\).
[14] One defines the generating function \(B(\theta) = \langle [\exp[-|\psi|^2(1 + e^{i\theta})]\rangle_p\). Then one computes the coefficient of \(B\) on the Fourier component \(e^{iN\theta}\), which gives the normalization factor of \(P_L\{\{\}\}\). A similar trick applies for the vortex density, so that \(\bar{\rho}_{v,c} = \int d^2 \theta \rho_{v,c} B(\theta) e^{-iN\theta}/\int d^2 \theta B(\theta) e^{-iN\theta}\) where \(\rho_{v,c}\) is taken from Eq. (4) replacing the mean occupation numbers \(n_m\) by \(\exp[\beta(\epsilon_m - \mu)] + \exp[\beta \mu]^{-1}\).
