Quantum capacitive phase detector

Leif Roschier, Mika Sillanpää, and Pertti Hakonen
Helsinki University of Technology, Low Temperature Laboratory, P.O. BOX 2200, FIN-02015 HUT, Finland

We discuss how a single Cooper-pair transistor may be used to detect the superconducting phase difference by using the phase dependence of the input capacitance from gate to ground. The proposed device has a low power dissipation because its operation is in principle free from quasiparticle generation. According to the sensitivity estimates, the device may be used for efficient qubit readout in a galvanically isolated and symmetrized circuit.

PACS numbers: 73.23.Hk, 85.35.Gv, 85.25.Cp

The interest in Coulomb blockade and accompanying quantum effects due to superconductivity has triggered a wave of research on new physics and future applications. One basic device is the single-electron transistor (SET) which consists of two small tunnel junctions having a sum capacitance of \(C_S\). If the single-electron charging energy \(E_C = e^2/(2C_S)\) dominates over temperature, \(E_C \gg k_B T\), the SET works as the most sensitive known electrometer.

In order to gain advantage of the inherently large bandwidth \((R_{SET}C_{S})^{-1} \sim 10\) GHz of the SET charge detector, two new technologies have been developed where the SET is read using an \(LC\) oscillator. The RF-SET (radio-frequency SET) is based on the gate dependence of the differential resistance of a sequential tunneling SET, a property which modulates the \(Q\)-value of the oscillator. No other device than the RF-SET has been able to track dynamic single-charge transport at MHz frequencies, which is relevant especially from the point of view of characterization and eventual single-shot readout of superconducting qubits.

Because of the limitations due to the dissipative nature of the RF-SET, a technique called L-SET (Inductive SET), having low dissipation, has been developed recently. With zero DC-voltage, a superconducting SET, henceforth called single Cooper-pair transistor (SCPT), behaves as an energy-storing reactive component because of the Josephson coupling \((E_J/2\) is defined as the single-junction Josephson energy).

Since the first energy band \(E_0\) of the SCPT grows approximately quadratically as a function of the drain-source phase difference \(\phi\), the SCPT behaves as an inductor when looked at from the source or drain. The effective Josephson inductance of a SCPT, \(L_J^{-1} = (2\pi/\Phi_0)^2 \partial^2 E_0/\partial \phi^2\), has a strong dependence on the (reduced) gate charge \(n_g = C_g V_g/(2e)\) if \(E_J/E_C \ll 1\). Here, \(\Phi_0 = h/(2e)\) is the flux quantum. In the L-SET schematics, a charge detector is built so that the resonance frequency of a system of a SCPT and an \(LC\) tank depends on \(n_g\). So far, we consider the L-SET the most promising method of sensitive and fast electrometry.

In addition to resistance or inductance, capacitance remains in the group of linear circuit elements. The first energy band of a SCPT grows approximately quadratically also with respect to the second external parameter \(n_g\). (A corresponding statement holds also for a single junction, which has been suggested in Ref. 3 as a capacitance tunable by injected charge.) Therefore, while observed from the gate electrode, the SCPT looks like an effective capacitance \(C_{\text{eff}}\) to ground. The operational principle of our proposal is based on the dependence of \(C_{\text{eff}}\) on the source-drain phase difference \(\phi\),

\[
C_{\text{eff}}(\phi) = \frac{\partial V_g}{\partial q_g(\phi)},
\]

where \(q_g\) is the charge on the gate capacitor, as illustrated in Fig. 3(a), (b). Note that in general \(q_g \neq C_g V_g\).

Once coupled to a tank circuit, modulation of \(C_{\text{eff}}(\phi)\) can be used to read a phase difference (henceforth, called simply phase) reactively in a reflection measurement (see Fig. 3). Phase is defined as the time integral of voltage, \(\phi = (2\pi/\Phi_0) \int_0^1 V dt\). In the superconducting case, \(\phi\) equals the order parameter phase.

Unlike any previous considerations of single-electron or single Cooper-pair devices, implementation of the "quantum capacitive phase detector" device proposed in the present paper is a generally fast and sensitive phase detector. We call the device a CSET, to emphasize its somehow dual operation with respect to the L-SET device.

Hamiltonian for a SCPT symmetric in its Josephson energies is

\[
H = E_{CP} \left( \frac{\partial}{\partial \theta} - n_g \right)^2 - E_J \cos(\phi/2) \cos(\theta),
\]

where a term \(C_g V_g^2/2\) and terms having \(\phi\) have been ignored. \(E_{CP} = (2e)^2/(2C_S)\) is the Cooper-pair charging energy and \(E_J/2\) is the Josephson coupling energy of the individual junctions. The phases are defined with the help of voltages \(V_i\) at points 1 and 2 in Fig. 1. \(\theta = (2\pi/\Phi_0) \int_0^1 (V_1 - V_2) dt\) and \(\phi = (2\pi/\Phi_0) \int_0^1 V_1 dt\). Here, the former is the difference and the latter is the sum of the phases over the two Josephson junctions.

The eigenvalues for this Hamiltonian are given by the solutions to the Mathieu equation when \(n_g \neq n/2\), where \(n\) is integer.
where \( M_A(r,q) \) is the characteristic value \( A \) for even Mathieu functions with characteristic exponent \( r \) and parameter \( q \). Unavoidable asymmetry of tunnel junctions in a real device is easily incorporated into Eq. (3). By substituting \( E_J \cos(\phi/2) \) in Eq. (3) by \( E_J \sqrt{(1 + d^2 + (1 - d^2) \cos(\phi))/2} \), we get energies of a SCPT whose individual junctions have unequal Josephson energies \( E_J(1 + d)/2 \) and \( E_J(1 - d)/2 \), where \( d \neq 0 \) is the asymmetry parameter. Junction capacitances, however, can be arbitrarily distributed. Fig. 2 illustrates the two lowest eigenvalues \( E_0 \) and \( E_1 \) with respect to the control parameters \( \phi \) and \( n_g \).

In order to calculate the observable capacitance \( C_{\text{eff}} \) from gate to ground when the system is in the lowest eigenstate \( E_0 \), we first calculate \( q_g = C_g(V_g - V_2) \), where the island voltage is \( V_2 = 1/C_g(\partial E_0/\partial V_g) \). Using Eq. (1) we have

\[
C_{\text{eff}} = \frac{\partial}{\partial V_g} \left( C_g V_g - \frac{\partial E_0}{\partial V_g} \right) = C_g - \frac{C_g^2}{C_Q},
\]

where \( C_Q \) is the quantum capacitance \( C_Q^{-1} = (\partial^2 E_0)/(2e^2 \partial n_g^2) \) due to the SCPT band structure. In the following analysis, the constant term \( C_g \) is neglected, because it is small compared with the shunting capacitance \( C_0 \).

In order to get maximum performance of the phase detector, we take the operation point of the device such that the transfer function \( \partial C_{\text{eff}}/\partial \phi \), which is the derivative of the capacitance modulation curves in Fig. 3, is maximized. This happens at \( \phi \) rather close to \( \pi \). As seen in Fig. 3, the transfer function increases rapidly at large \( E_J/E_{CP} \). The price to pay for a high gain then is a limited dynamic range. The external gate drive is taken as \( V_g(t) = V_{g0} \cos \omega_0 t \).

Asymmetry in the SCPT weakens the modulation considerably at high \( E_J/E_{CP} \geq 3 \) as seen in Fig. 3 (dashed lines). This is because asymmetry removes the degeneracy at \( n_g = \pm 0.5 \) and \( \phi = \pm \pi \) and smooths out the

\[
E_k(\phi, n_g) = \frac{E_{CP}}{4} M_A \left( k + 1 - (k + 1)[\text{mod} \, 2] + 2n_g(-1)^k \frac{2E_J \cos(\phi/2)}{E_{CP}} \right), \tag{3}
\]
Because it takes $Q$ cycles for the (loaded) resonator to dissipate most of its stored energy, the reflected power flow is

$$P \approx E f_0 / Q = \frac{f_0 e^2 C}{8 Q C_g^2}. \quad (7)$$

This is about 5 fW with typical parameters in an experiment. The voltage amplitude of the modulation is $\Delta V = \Delta \phi V_c$, where the carrier voltage amplitude is $V_c = \sqrt{2Z_0 P}$. The modulation is conveniently transformed into power units to enable later comparison with noise power. This leads to the definition of information power:

$$P_i = \frac{(\Delta V)^2}{2Z_0} = \frac{(\Delta \phi)^2 V_c^2}{2Z_0} = (\Delta \phi)^2 P. \quad (8)$$

By combining Eqs. (6), (7) and (8), we find

$$P_i \approx Q \left(\frac{\Delta C}{C_0}\right)^2 \frac{f_0 e^2 C}{2C_g^2}. \quad (9)$$

Eq. (6) may be written in terms of the transfer function $\partial C_\text{eff} / \partial \phi = C_\text{eff}^2 \partial^3 E_0 / (4e^2 \partial \mu h^2 \partial \phi)$, $C_0$, and $Z_0$. We also approximate $C_\text{eff} \ll C_0$. It follows

$$P_i(\Delta \phi) \approx \frac{1}{64 \pi Z_0 e^2} \left(\frac{\partial^3 E_0}{\partial \mu h^2 \partial \phi}\right)^2 \left(\frac{C_g}{C_0}\right)^2. \quad (10)$$

Sensitivity increases dramatically by increasing the $E_1/E_{CP}$ ratio as illustrated in Fig. 3. $E_{CP} \gg k_B T$ must be satisfied in order to keep the system localized in the lowest state $E_0$. At a fixed ratio of $E_1/E_{CP}$, maximization of $C_g/C_0$, and minimization of $Z_0$ yields the best sensitivity.

In order to estimate device performance we take the operation frequency $f_0$ to be $\sim 1$ GHz. The individual component values are chosen to be easily realizable by present fabrication technology. Due to stray capacitance from bonding pads etc., it is difficult to achieve in practice $C_g$ lower than $\sim 0.15$ pF. To have a series resonance at the $f_0$ with Q-factor of $\sim 20$, this would be accompanied by an inductance $L \sim 160$ nH. The inductance may be easily realized by using a commercial surface mount coil. It is to be noted that the capacitance $C_\text{eff}$ is $\sim 1/75$ of the capacitance $C_0$ assuming a large $C_g \sim 2$ fF. The large gate capacitance is easily implemented with a similar overlap junction as the two SCPT tunnel junctions, but using a much longer oxidation to create a highly resistive junction.

For phase sensitivity estimates, we calculated $\Delta C / C_0$ resulting from a phase change $\Delta \phi = 1$ rad, at different ratios of $E_1/E_{CP}$, and assuming $E_{CP} = 1$ K. They are listed in Table 3. The values are calculated at the optimal
TABLE I: Linearized relative change of capacitance corresponding to a $\Delta \phi = 1$ rad, for symmetric SCPT (parameters as in the text).

| $E_j/E_{CP}$ | 0.1 | 0.3 | 1 | 3 | 10 |
|---------------|-----|-----|---|---|----|
| $\Delta C/C_0$ | $8.5 \times 10^{-5}$ | $6.6 \times 10^{-4}$ | $4 \times 10^{-3}$ | $1.1 \times 10^{-2}$ | $4.3 \times 10^{-2}$ |

operation point of $\phi$ which maximizes the transfer function, and at $V_g \sim 0$. As seen in Fig. 1, the information power is $P_i \sim 10$ fW with $E_j/E_{CP} \sim 10$.

By using a cryogenic HEMT amplifier with a typical noise temperature of 3 K that corresponds to spectral density of $s_N \sim 4 \times 10^{-23}$ W/Hz, we find the phase sensitivity $s_\phi = \sqrt{s_N/P_i(1 \text{rad})}$ of the order 45 $\mu$rad/$\sqrt{\text{Hz}}$ for symmetric SCPT. Combined with a low-noise SQUID amplifier that would be close to the resonator circuit, the value $Z_0$ could be lowered to a value of 1 $\Omega$ or below $\langle 1 \rangle$ and the noise temperature could be down by a factor 30. This would result in a sensitivity of 1.3 $\mu$rad/$\sqrt{\text{Hz}}$.

Asymmetry in the SCPT junctions weakens the numbers at high $E_j/E_{CP}$, as portrayed by the dashed line in Fig. 1. With $E_j/E_{CP} = 10$ and $d = 0.1$, the mentioned sensitivities would go down by a factor of 5. However, at high $E_j/E_{CP}$ the junctions are naturally of large area, and hence relatively easy to fabricate with similar sizes.

FIG. 4: Information power (Eq. 10) corresponding to a phase modulation $\Delta \phi = 1$ rad. Solid line: symmetric SCPT ($d = 0$); dashed line: slightly asymmetric SCPT ($d = 0.1$). Other parameters are as given in the text.

For the estimates discussed here, we have assumed operation of the device only at ”safe” values of $V_g$. That is, variation of the capacitance $C_{\text{eff}}$ is continuous over a reasonable range of values around the operation point. As evident in Fig. 2, close to the degeneracy points, the differential change of capacitance is substantially larger. One needs, however, a relatively strong AC gate drive $V_{g0}$ in order to distinguish the carrier signal from the pre-amplifier noise power within the bandwidth. For this reason, we have omitted the analysis of these points.

In order to demonstrate an important application of the CSET, we discuss a circuit, where the CSET works as a detector for the state of the charge-phase qubit (see Fig. 5).

FIG. 5: Schematic of the CSET coupled to a charge-phase qubit $\langle 12 \rangle$. The gauge-invariant phase differences $\gamma_i$ and their orientations are marked with arrows. All Josephson junctions are taken to have same Josephson coupling energy $E_J/2$. $\Phi$ is the externally applied magnetic flux.

The basic idea of this circuit is that since the qubit states $|0\rangle$ and $|1\rangle$ correspond to distinct phases $\phi$, they result in a different capacitance of the CSET phase detector.

Due to a supposed large capacitance, $C_s \gtrsim 20 \mu$F, phases with respect to ground at points A and B are taken as classical variables. Charging energy of these leads is neglected for the same reason. The structure having this high capacitance is naturally fabricated on a ground plane substrate. For a standard insulator thickness of 300 nm on top of a conducting ground plane, the loop structure would measure only tens of $\mu$m in size.

We assume that the circuit can be described as two connected SCPTs (detector and qubit) and that the gauge-invariant phase $\gamma_i$ over each of them is found by solving the equations

$$\gamma_1 + \gamma_2 = -2\pi \Phi/\Phi_0(\text{mod } 2\pi), \quad (11)$$

and

$$\frac{\partial E_{k'}}{\partial \gamma_1}(\gamma_1, V_{g1}) = \frac{\partial E_{k2}}{\partial \gamma_2}(\gamma_2, V_{g2}). \quad (12)$$

The former equation assures the correct $2\pi$-periodicity of the sum of the phases around the loop. The latter equation states that the currents flowing through both SCPTs have the same magnitude. The energies $E$ are defined according to Eq. (3). The band index $k'$ for the detector is always null and the qubit index $k$ takes values 0 or 1, corresponding to the states $|0\rangle$ and $|1\rangle$. For this
example we assume for simplicity that both SCPTs have \( E_f/E_{CP} = 1 \).

As an example of the operation we suppose that after manipulating the qubit, it is in a superposition which then collapses into either \(|0\rangle\) or \(|1\rangle\) when the detector is turned on. The detector, on the other hand, stays in the state \(|0\rangle\). In order to start the measurement, the qubit gate voltage is turned to approximately \( C_g V_{g2}/2e = 0.37 \). The detector is maintained at \( C_g V_{g1}/2e = 0 \) throughout the operations. Thereafter, an externally applied magnetic flux is ramped adiabatically to \( \Phi/\Phi_0 \approx 1/2 \).

Fig. 5 illustrates the dependence of \( \gamma_1 \) with respect to the qubit state. Depending on the state of the qubit, the phase over the detector circuit \( \gamma_1 \) will thus become either 0 or \( \sim -2 \) rad. According to Fig. 5, the capacitance \( C_{eff} \) then differs by \( \sim 0.4 \) fF, depending on the qubit final state. According to Eq. 5, the difference corresponds to an information power of \(-132 \) dBm, by using easily achievable values \( C_0=0.15 \) pF, \( Q=20 \), \( f_0=1 \) GHz and \( C_g=2 \) fF. Signal-to-noise-ratio 1 is then achieved at a bandwidth of 20 MHz with a feasible SQUID first stage amplifier having a noise temperature of 0.3 K. Measurement is thus clearly possible in sub-microsecond regime. A reasonable junction asymmetry, \( d = 0.1 \) has a negligible influence on the curves in Fig. 5.

The proposed qubit circuitry has several important advantages. First, low power dissipation means low rate of quasiparticle generation, which is essential for low back-action and fast recovery from the measurement. Second, since the circuit is galvanically isolated, it is free from external quasiparticle injection.

The third advantage is the symmetry of the schematics. Although in some sense the circuit is strongly coupled to the external \( Z_0 \) via the detector gate, thermal noise of \( Z_0 \) acts only as a common-mode signal. This is equivalent to say that the real part of the impedance seen by the qubit \( \text{Re}(Z) \) is very small. Asymmetry weakens the situation, but with a realistic, random asymmetry of about 20% in the component values, we calculated the following figures in the schematics of Fig. 6 that \( \text{Re}(Z) \ll 1 \) mΩ both at low frequency \( (f < 1 \) GHz) which is relevant for dephasing, and at the level-spacing frequency \((10 - 50 \) GHz) which affects relaxation. Especially since the qubit operations are naturally performed at the saddle point \( \phi = 0 \), \( n_g = \pm 1/2 \) similarly as in the original charge-phase qubit, the system is extremely well decoupled from the environment. Note that the gate and flux operation leads of the qubit may be weakly coupled so that they do not contribute noise.

Coherence time is then presumably limited by internal 1/f noise, which should be similar to existing qubit realizations. Its effect weakens as \( E_{CP} \) grows. At a conservative value \( E_{CP} = 1 \) K, we estimate a dephasing time \( \tau_\phi \) of \( 1 - 2 \mu s \), which is comparable to the original charge-phase qubit.

In conclusion, we have proposed a technique to measure the superconducting phase difference by monitoring the effective capacitance between the gate of a single Cooper-pair transistor and ground. As a practical example, the readout of a charge-phase qubit using the technique was discussed.

Fruitful discussions with T. Heikkilä, N. Kopnin and T. Lehimen are gratefully acknowledged. This work was supported by the Academy of Finland and by the Large Scale Installation Program ULTI-3 of the European Union.

![Fig. 6: Dependence of the phase over the detector \( \gamma_1 \) on the applied magnetic flux \( \Phi \). The thick (blue) lines correspond to the solutions of Eqs. (11) and (12), when the qubit is in the state \(|0\rangle\). The thin (red) lines are for the qubit state \(|1\rangle\), respectively.](image)
