(Dated: January 8, 2016)

The ferrimagnetic spinel CoV$_2$O$_4$ has been a topic of intense recent interest, both as a frustrated insulator with unquenched orbital degeneracy and as a near-itinerant magnet which can be driven metallic with moderate applied pressure. Here, we report on our recent neutron diffraction and inelastic scattering measurements on powders with minimal cation site disorder. Our main new result is the identification of a weak ($\Delta \sim 10^{-4}$), first order structural phase transition at $T^* = 90$ K, the same temperature where spin canting was seen in recent single crystal measurements. This transition is characterized by a short-range distortion of oxygen octahedral positions, and inelastic data further establish a weak $\Delta \sim 1.25$ meV spin gap at low temperature. Together, these findings provide strong support for the existence of an orbital glass state at temperatures below $T^*$.

I. INTRODUCTION

The spinel vanadates, AV$_2$O$_4$, are interesting materials which lay at the heart of several distinct topics in condensed matter physics. In recent years, the focus has been geometric frustration, and the role played by the vanadium orbital angular momentum degrees of freedom in relieving the significant spin frustration inherent to the spinel structure. In insulating vanadates containing divalent A-site cations, the octahedrally coordinated V$^{3+}$ comprise a pyrochlore sublattice with $S = 1$ spins and an orbital triplet degeneracy in the ideal cubic crystal field environment. When the A$^{2+}$ cation is non-magnetic, this degeneracy is resolved at a Jahn-Teller structural transition from cubic-to-tetragonal global symmetry, followed by an antiferromagnetic spin order transition upon cooling. In materials MnV$_2$O$_4$ and FeV$_2$O$_4$, the A-site also contains a spin, and $A-B$ superexchange interactions stabilize a form of collinear spin order, before orbital order transitions simultaneously distort the cubic structure and cant spins at lower temperatures. CoV$_2$O$_4$ is a unique case. Though a collinear ferrimagnetic transition near $T_{N1} = 150$ K has long been observed and there have been recent reports suggesting a weaker spin canting transition near $T_{N2} = 90$ K, the material is reported to retain cubic global symmetry to lowest measured temperatures. This last observation is especially interesting, as it contradicts all known models for this class of materials. We discuss it in more detail below.

Enhanced spin-lattice coupling and associated phenomena resulting from orbital order have been reported on several occasions, and theory has predicted a number of different ordering patterns. Given the difficulty of accessing the orbital order parameter experimentally, conclusions have been argued indirectly, and debate has centered on the relative importance of exchange, spin-orbit coupling and various crystal field terms in the magnetic Hamiltonian. A secondary line of debate has focused on whether localized orbital models are appropriate at all, or whether one should approach the problem from the itinerant limit for some materials. Indeed, the spinel vanadates were initially studied in the context of localized-itinerant crossover physics, and are predicted to be metallic for V-V separations ($R_{VV}$) less than the critical distance of $R_c = 2.97$ Å. Though known materials are all semiconductors, those with $R_{VV} < R_c$ (e.g. MgV$_2$O$_4$, ZnV$_2$O$_4$ and CoV$_2$O$_4$) have enhanced electron-lattice coupling and transport properties best described by the hopping of polarons. The activation energy of polarons is seen to decrease sharply (i.e. materials become more metallic) with decreasing $R_{VV}$ and increasing pressure, but increase with disorder due to cation inversion or mixed valence on the spinel B-site. Since CoV$_2$O$_4$, which has the shortest $R_{VV}$, has been driven metallic over a limited temperature range with an applied pressure of 6 GPa.

Recent studies have expounded on the role played by the proximate itinerant state. One study showed that, although materials CdV$_2$O$_4$ and Mn$_2$V$_2$O$_6$ are well described by insulating models, the $Mn$ compound exhibits anomalously high compressibility which has been argued to signify a breakdown of the Mott-Hubbard picture. Materials with shorter $R_{VV}$ ($A \in \{Fe, Zn, Mg, Co\}$) may lay in an intermediate phase, characterized by partial delocalization, mobility of large polarons and short-range magnetic order. These arguments seem to be backed
by first principles calculations in CoV₂O₄, which suggest the coexistence of localized and itinerant electrons, and electronic structure calculations in ZnV₂O₄, which explain the low-temperature transitions as a structural instability toward V-V dimerization, with no role for local orbital. The role of orbital order in near-itinerant vanadates was further challenged by studies of the doping series Mn₁₋ₓCoxV₂O₄, where x-ray and heat capacity measurements reveal the suppression of the low-temperature tetragonal phase transition above critical doping \( x_c \approx 0.8 \) and neutron scattering reveals the decoupling of this transition from spin canting.

In light of the above discussion, the case of CoV₂O₄ is particularly intriguing. This material is a direct analogue to MnV₂O₄, forming a near ideal spinel structure with V³⁺ on the pyrochlore lattice and spin-only S=3/2 Co²⁺ on the A-site. Its near critical V-V separation has made it the subject of several studies exploring the role of the proximate itinerancy in 3d magnet systems. Though it is well-established that there exists a magnetic transition to a near collinear ferrimagnetic ordered state below \( T_N \approx 150 \)K, the experimental situation at lower temperatures is quite unclear. While one study of CoV₂O₄ powders reported a cusp in magnetization near \( T = 100 \) K and a sharp peak in heat capacity at \( T = 60 \) K, similar measurements of a single crystal sample revealed only a magnetic anomaly at \( T = 75 \) K and no signature in heat capacity at any temperature below \( T_N \). Neither study saw a deviation from cubic symmetry down to \( T = 10 \) K, which itself is surprising, as both orbital order and dimerization models predict a symmetry lowering structural transition. Very recently, a neutron and strain study of crystals and powders enriched with excess cobalt reported a spin canting transition \( T_{N2} = 90 \) K, which it associated with the onset of an orbital glassiness, and a separate structural transition of unknown origin near \( T = 40 \) K.

The large variation in the literature is likely a reflection of the combined weakness of observed effects and the enhanced sensitivity of this material to disorder. The differing heat capacity signatures in powders and crystals has been ascribed to the presence of random fields differing heat capacity signatures in powders and crystals, and to Mn-V at \( T = 90 \) K, which they associated with the onset of an orbital glassiness, and a separate structural transition of unknown origin near \( T = 40 \) K.

II. MATERIALS PREPARATION AND EXPERIMENTAL DETAILS

Powder samples of CoV₂O₄ were prepared via solid state reaction at the National High Magnetic Field Lab in Tallahassee, FL, and extensive characterization data can be found on related samples in Refs. 27 and 43. As discussed above, these references report a near cubic structure to lowest temperatures and the formation of a net ordered moment below 150K, reflecting the ferrimagnetic spin order known from previous neutron measurements. Neutron scattering data in the current report was obtained entirely using instruments at Oak Ridge National Laboratory (ORNL) in Oak Ridge, TN. Powder diffraction work was performed using the HB2A instrument at the High Flux Isotope Reactor (HFIR) followed by wide-angle time-of-flight (TOF) measurements using the Nanoscale-Ordered Materials Diffractometer (NOMAD) instrument at the Spallation Neutron Source (SNS). HB2A measurements were performed using ~3g of powder, placed in a vanadium can with helium exchange gas to ensure cooling. Patterns were measured independently with \( \lambda = 1.538 \)A and \( \lambda = 2.41 \)A neutrons from a germanium monochromator, and fit simultaneously. For NOMAD measurements, about 100 mg of sample was measured in 6 mm diameter vanadium cans for 20 minutes in an ILL Orange cryostat. NOMAD detectors were calibrated using scattering from diamond powder, and the instrument parameter file for the Rietveld refinements was obtained from the measurements of the NIST standard silicon powder. The structure factor S(Q) was obtained by normalizing diffraction data against a solid V rod, and subtracting the background using the IDL routines developed for the NOMAD instrument. The pair-distribution function (PDF) was obtained by the Fourier transform of S(Q) with \( Q_{max} = 31.5 \)A⁻¹:

\[
G(r) = \frac{2}{\pi} \int_{Q_{min}}^{Q_{max}} Q(S(Q) - 1) \sin(Qr)dQ
\]
Rietveld refinements were performed using Fullprof\textsuperscript{52} and PDF fits were performed using the PDFgui software\textsuperscript{53}.

Inelastic neutron scattering (INS) measurements were performed using the hybrid spectrometer HYSPEC at the SNS. HYSPEC is a highly versatile direct geometry spectrometer that combines TOF spectroscopy with the focusing Bragg optics\textsuperscript{54}. The incident neutron beam is monochromated using a Fermi chopper with short, straight blades, and is then vertically focused by Bragg scattering onto the sample position by highly oriented pyrolytic graphite. HYSPEC employs 3He linear position sensitive tube detectors that are assembled into 20 sets of 8-packs that cover an angular range of 60\degree in the horizontal scattering plane and a vertical acceptance of 15\degree. For the INS measurements, the CoV\textsubscript{2}O\textsubscript{4} powder was loaded in an aluminium can and placed in a closed cycle refrigerator capable of reaching a base temperature of 5 K. Data was collected with incident energies $E_i = 60$ meV, 35 meV, 15 meV and 7.5 meV, and Fermi chopper frequencies of 300 Hz, 180 Hz, 180 Hz and 420 Hz, respectively.

III. NEUTRON SCATTERING RESULTS

A. Powder Diffraction

Neutron powder diffraction measurements were first performed using the HB2A instrument with two neutron wavelengths, and main results are shown in Figure 1. Figs. 1(a)-(c) shows patterns from 1.54\AA measurements at $T = 280$ K, 115 K and 4 K, along with lines showing best-fit Rietveld refinements, performed using both wavelengths. Refinement of the pattern at $T = 280$ K (Fig. 1(a)) confirms the near ideal spinel structure, with approximately 4% of the vanadium sites containing cobalt cations. Patterns at lower temperatures (Fig. 1(b)-(c)) exhibit a visible increase in the intensity of several low-angle peaks associated with collinear ferrimagnetism, most prominently the cubic (111). Targeted measurement of this peak over a range of temperatures resulted in the data in Fig. 1(d), and simple power-law fits yield a transition temperature of $T_N = 156.1 \pm 0.5$ K. A complete listing of refinement parameters for each of the four measured temperatures is listed in Table I.

B. TOF Diffraction and Pair-Distribution Function Analysis

To search for local distortions of oxygen octahedra or other signatures of orbital glassiness, we supplemented
The existence of a structural transition at $T^* = 90$ K is particularly important in light of previous polarized neutron scattering work on single crystals, which has established that a spin-canting transition exists at the exact same temperature. Our own diffraction data is also not inconsistent with such a conclusion. In Table I, we show refined magnetic moments at selected temperatures assuming the canted state described above. One can see a smooth development of ferrimagnetism below $T_N$, with moment sizes (Fig. 2(c.)) equal within error to HB2A fits and an implied canting angle for vanadium spins of 15 ± 5° at base temperature. This canting angle is statistically significant, though larger than implied by single crystal measurements in Ref. 29 but notably equal to results from powder refinements in the same study. In Fig. 2(f.), we show the temperature variation of $M^2_{V,\perp}$, which is proportional to the cubic (200) Bragg peak intensity, used in Ref. 29 to detect the spin canting transition in single crystals of this material. Though the magnitude of $M^2_{V,\perp}$ (and thus canting angle) seems to grow with decreasing temperature, statistical error bars in our data set are too large to discern a clear kink at $T = T^*$. We do note, however, that the total increase of $M^2_{V,\perp}$ over the measured temperature range is the same as seen in Ref. 29. If one assumes a transition, fits to a power-law temperature dependence yield $T^* = 92 K \pm 5 K$. Thus, we conclude that our data is consistent with the previously reported spin canting transition at $T^*$. In light of this, the coincident structural transition seen in the current data set strongly suggests that this temperature can be associated with the ordering of $V^{3+}$ orbitals.

The same data set was subject to a PDF analysis, using the transform given by Eq. 1 and assuming a cubic spinel structure. The main results, shown in Fig. 3, tell a similar story to the one above. The cubic spinel structure describes the data well at all temperatures (see, e.g., Fig. 3(a.)), and there is a distinct jump in the inferred lattice parameter and the atomic displacement parameter of oxygen atoms at $T^* = 90$ K. Fits were performed over a number of increasingly shortened ranges in real-space: $1.5 \AA < R < R_{\text{max}}$, with $R_{\text{max}}$ varying from 30Å to 15Å. Additionally, one fit was performed using a range $10 \AA < R < 45 \AA$, to explicitly suppress the effect of local correlations. As shown in Fig. 3(b.), the magnitude of the jump in lattice parameter at $T = T^*$ was found to be largely independent of fit range, consistent with expectations for a true long-range effect. In contrast, the displacement of the oxygens decreases monotonically with increasing $R_{\text{max}}$ and is strongly suppressed for the fit where local correlations are neglected. This suggests that the atomic displacement parameter of oxygens (Fig. 3(c.)) has an overwhelmingly local character. As this parameter represents the root mean square positions of oxygens forms-

| T (K) | a (Å) | $x_{O2-}$ | $M_{Co}$ (μB) | $M_{V,\parallel}$ (μB) | $M_{V,\perp}$ (μB) |

TABLE II: Fit parameters at selected temperature, extracted from Rietveld refinements of NPD patterns taken using the NOMAD instrument at the SNS. Details about the fit model are provided in the main text, and further parameters for the entire temperature range can be found in the Supplemental Materials.
FIG. 2: Main results from a Rietveld refinement of diffraction data taken with the NOMAD instrument. TOF data were fit to the ideal cubic structure and the canted spin model described in the main text. Panel (a.) shows a typical pattern from data collected using a single NOMAD detector bank. Here, the solid line shows the best fit to the above model. The temperature dependence shows a jump in the fit lattice parameter (panel (b.)) and atomic displacement parameter for oxygens (panel (c.)) at the same temperature, $T^* = 90$ K. Neither the fractional position parameter for the oxygens (panel (d.)), nor the ordered moment sizes (panel (e.)) show a signature at $T^*$. Panel (f.) is the square of the transverse $V^{3+}$ ordered moment, equivalent to the cubic (200) Bragg peak, commonly thought to indicate spin canting. Solid line in this panel is a fit to a power-law temperature dependence, and implies $T^* = 92\pm5$ K.

FIG. 3: Results of a PDF analysis of the NOMAD data, assuming a cubic spinel structure and neglecting scattering from spin order. Panel (a.) shows a typical fit at base temperature, demonstrating the ability of the model to describe the PDF patterns. Panels (b.) plot the refined lattice parameter as a function of temperature, as inferred from fits of real space data over several distinct data ranges. From top to bottom, data was fit using the range 1 $\text{Å} < R < R_{\text{max}}$, for $R_{\text{max}} = 15$ Å, 20 Å, and 35 Å, whereas the bottom panel used 10 $\text{Å} < R < 45$ Å. Panels (c.) show equivalent plots of the oxygen ADP. Both sets of panels reveal a discontinuity at $T^* = 90$ K, but exhibit a different dependence on fit range, as discussed in the main text.

(b.) show the low-energy magnon spectra at $T = 6$ K, taken with $E_i = 15$ meV and 7.5 meV neutrons, respectively. Immediately apparent is the existence of a highly-dispersive, bright excitation mode emerging out of the position $Q = 1.3\text{Å}^{-1}$, which is associated with the cubic (111) Bragg peak. Closer inspection reveals weaker excitations emerging from $Q = 1.5\text{Å}^{-1}$ and $Q = 2.1\text{Å}^{-1}$, the location of the (200) and (220) peaks, respectively. Figs. (c.) and (d.) confirm that these excitations give

C. Inelastic Neutron Scattering

Further support for an orbital glass picture comes from inelastic neutron measurements on the HYSPEC spectrometer, summarized in Figs. 4 and 5. Figs. 4(a.) and (b.) show the low-energy magnon spectra at $T = 6$ K, taken with $E_i = 15$ meV and 7.5 meV neutrons, respectively. Immediately apparent is the existence of a highly-dispersive, bright excitation mode emerging out of the position $Q = 1.3\text{Å}^{-1}$, which is associated with the cubic (111) Bragg peak. Closer inspection reveals weaker excitations emerging from $Q = 1.5\text{Å}^{-1}$ and $Q = 2.1\text{Å}^{-1}$, the location of the (200) and (220) peaks, respectively. Figs. 4(c.) and (d.) confirm that these excitations give...
way to a correlated paramagnetic phase at temperatures \( T > T_N \). The flat band of scattering in Fig. 4(b.) is seen only with \( E_i = 7.5 \) meV, but not with \( E_i = 15 \) meV (Fig. 4(a.)), 35 meV, or 60 meV (Fig. 5(a.)). For this reason, we conclude it is likely spurious, though its origin is unknown.

Plots of scattering intensity versus energy transfer reveal a small peak in scattering at \( \Delta \sim 1.25 \text{meV} \) above both magnetic Bragg peaks, which is suggestive of a spin gap. Though we are unable to confirm the complete absence of scattering at lower energies due to experimental constraints, the magnitude of this gap is nearly a factor of 2 smaller than reported for \( \text{Mn}_{2-x}\text{Co}_x\text{V}_2\text{O}_4 \) for \( \text{Co}^{2+} \) concentrations up to \( x = 0.4 \). This is consistent with expectations for an orbital order state with strong renormalization due to proximate itinerancy.

In Fig. 6 we show a comparison of inelastic data taken with \( E_i = 60 \text{meV} \), and simulations based on a semiclassical spinwave Hamiltonian:

\[
H = \sum_{<i,j>} J_{i,j} \mathbf{S}_i \cdot \mathbf{S}_j + \sum_i D_i (\mathbf{S}_i \cdot \mathbf{n}_i)^2, \tag{2}
\]

along with the parameters in Table III. Here, the sums are over all spins, including both cation sites, and interactions are truncated beyond nearest neighbors for the \( \text{Co}^{2+} \) sites (nearest neighbor \( \text{Co-V} \) interactions) and next-nearest neighbors for the \( \text{V}^{3+} \) sites (nearest neighbor \( \text{V-V} \) and nearest neighbor \( \text{Co-V} \) interactions only).

We have used \( J_{AB} \) to denote the exchange interaction between A-site cobalt and B-site vanadium spins, while \( J_{BB} \) (\( J_{BB}' \)) describes interactions between nearest-neighbor vanadium spins with the same (different) \( c \)-axis positional coordinates. Single-ion anisotropy was set to zero for cobalt (\( D_A \)), consistent with the near-cubic structural symmetry, and fixed along local \( <111> \) directions for the vanadium sites (\( D_B \)). A similar analysis was successfully used by us to describe spin excitations in \( \text{FeV}_2\text{O}_4 \) and in Ref. 45 to describe the \( \text{Mn}_{1-x}\text{Co}_x\text{V}_2\text{O}_4 \) family of compounds.

Notably, the material parameters listed in Table III and used to create Fig. 6(b.) were not extracted from fits to the inelastic data (Fig. 5(a.)), but rather were extrapolated from parameters reported for single-crystalline \( \text{Mn}_{0.4}\text{Co}_{0.6}\text{V}_2\text{O}_4 \) and adjusted to account for Néel temperature, canting angle and spin gap. It should be pointed out then that the Heisenberg exchange parameters in \( \text{Mn}_{0.4}\text{Co}_{0.6}\text{V}_2\text{O}_4 \) are hugely anisotropic, as interactions between V-V pairs in that material are strongly modified by the existence of orbital order and the associated structural distortion. Specifically, orbital order results in \( J_{BB} \) and \( J_{BB}' \) that differ significantly not only in magnitude, but also sign. Though the lattice structure in \( \text{CoV}_2\text{O}_4 \) is more isotropic, we found we were unable to satisfactorily describe the inelastic data in Fig. 5 without retaining the anisotropy in the Heisenberg exchange parameters, and specifically the difference in sign between \( J_{BB} \) and \( J_{BB}' \). The significance of this observation is discussed in more detail below.

Even without fitting, this basic spinwave model is able to account for several specific features of the \( \text{CoV}_2\text{O}_4 \) data, including the minima at 1.3 \( \text{Å}^{-1} \) and 1.5 \( \text{Å}^{-1} \), the ridge of intense scattering between 14 \text{meV} \) and 20 \text{meV}, and the second ridge of scattering near 37 \text{meV}. Arguably, the largest failure of the model is an overestimation of scattering at higher \( Q \), including the prediction of an intense mode near \( Q = 3.0 \text{Å}^{-1} \). This observation indicates a deviation in \( \text{CoV}_2\text{O}_4 \) from the assumed spherical approximation for the local magnetic form factor, and in fact may indicate that the atomic orbitals are distributed over larger distances in real space, as one might expect.
for a material approaching an itinerant crossover.

IV. DISCUSSION AND CONCLUSIONS

Collectively, the neutron scattering results presented here draw a clear and consistent picture for the physics underlying CoV$_2$O$_4$. The most striking new result is the first order structural phase transition at $T^* = 90$K, which by itself addresses the largest outstanding question in the study of this material—namely the unexpected preservation of the high symmetry cubic phase to lowest temperatures. Here, we see that the predicted symmetry lowering transition is not absent, but has merely been suppressed in magnitude to $\Delta_0 \sim 10^{-4}$, presumably another effect of the near-itineracy. The subtlety of the transition and our inability to resolve details of the low symmetry structure does not allow us to strictly determine whether it is driven by orbital order or an instability towards homopolar bond formation. If one takes into account, however, previous reports of spin canting at the same temperature and the small spin gap seen in powder inelastic data at base temperature, the experimental situation surrounding CoV$_2$O$_4$ is strongly reminiscent of other ferrimagnetic spinels more unambiguously described by the Mott insulating picture. Thus, it seems most appropriate to describe the 90 K transition in CoV$_2$O$_4$ as an ordering transition for localized $V^{3+}$ orbitals. In further support of this idea, we note that our successful description of inelastic scattering invoked a localized spin Hamiltonian, and used parameters which imply a strong anisotropy in Heisenberg exchange parameters. This magnetic anisotropy echoes previous reports of an anisotropic compression in single crystal. Without a much larger tetragonal distortion than what we are reporting, the most natural way of explaining these experimental signatures is though an emergent electronic anisotropy, such as one expects in an orbitally ordered state.

On a final note, we point out that our data allows us to rule out any additional structural or spin transitions below $T^*$, within the sensitivity of our probe. This is in direct contrast to reports of transitions at 40 K or 75 K seen in both powders and single crystals. We believe the variation on this point in the literature is largely a result of the difficulty in preparing pure samples of this material and its peculiar sensitivity to disorder. It is known that the most frequent impurity phase in the preparation of CoV$_2$O$_4$ is V$_2$O$_3$, which is strongly correlated and has transition temperatures which are sensitive to level of defects. On the other hand, it is also known that the presence of excess cobalt on the vanadium site strongly affects the degree of localization in this material, drives changes in Neel temperature, and has led to at least one report of a transition between 45 K and 70 K which disappears upon annealing. Moreover, it has been suggested that enhanced sensitivity to disorder as materials approach the itinerant crossover affects both the level of localization and might further explain the many reports of glassy correlations and X-ray and neutron diffraction measurements on our samples reveal no detectable impurity phases and a cation inversion ($x \sim 0.04$) that is among the lowest in the literature, which increases confidence in our results. A systematic multi-sample study will probably be required, however, to disentangle complicated disorder effects in this material and discern the true number of transitions.

In summary, we have presented strong evidence for a structural phase transition in CoV$_2$O$_4$ at a temperature of $T^* = 90$K. This transition, coupled with previous reports of spin canting and the presence of a spin gap, lead us to believe that this material is best described by a local orbital ordering picture, though it is certainly possible that ferrimagnetic bond formation is playing a role. We suggest that the main effects of the nearby itinerant state are the strong reduction of the magnitude of the structural distortion, the reduction of the vanadium ordered moment and canting angle associated with the

orbital order, and the modification of the magnetic form factor, indicative of a near delocalized spin distribution. Confirmation of these interpretations could come from future pressure experiments, where the known insulator-metal transition should completely suppress the reported structural transition and spin gap.
