Molecular imaging of oncolytic viral therapy

Dana Haddad1 and Yuman Fong2

Oncolytic viruses have made their mark on the cancer world as a potential therapeutic option, with the possible advantages of reduced side effects and strengthened treatment efficacy due to higher tumor selectivity. Results have been so promising, that oncolytic viral treatments have now been approved for clinical trials in several countries. However, clinical studies may benefit from the ability to noninvasively and serially identify sites of viral targeting via molecular imaging in order to provide safety, efficacy, and toxicity information. Furthermore, molecular imaging of oncolytic viral therapy may provide a more sensitive and specific diagnostic technique to detect tumor origin and, more importantly, presence of metastases. Several strategies have been investigated for molecular imaging of viral replication broadly categorized into optical and deep tissue imaging, utilizing several reporter genes encoding for fluorescence proteins, conditional enzymes, and membrane protein and transporters. Various imaging methods facilitate molecular imaging, including computer tomography, magnetic resonance imaging, positron emission tomography, single photon emission CT, gamma-spectroscopy, and photoacoustic imaging. In addition, several molecular probes are used for medical imaging, which act as targeting moieties or signaling agents. This review will explore the preclinical and clinical use of in vivo molecular imaging of replication-competent oncolytic viral therapy.

Molecular Therapy — Oncolytics (2015) 1, 14007; doi:10.1038/mto.2014.7; published online 4 February 2015

WHY ONCOLYTIC VIRUSES FOR GENE DELIVERY?

Oncolytic viruses refer to those that are able to preferentially and selectively propagate in cancer cells, and consequently destroy tumor tissues leaving noncancerous tissues unharmed (Figure 1).9 The idea that viruses may be able to treat cancer was born almost by chance, when in the early 20th century patients with malignancies who experienced viral infection or received rabies vaccinations were noted to experience transient remissions.6,10 These early discoveries led to several viruses being tested in both preclinical and clinical settings during the late 1940s, 50s, and 60s.12 While early studies and clinical trials were considered groundbreaking, interest in viruses as potential antineoplastic therapies was abandoned due to unimpressive and short-lived success, as well as unacceptable side effects that eventually ended trials.13 It is only in the last two decades or so that the fervor of viruses as a strategy against cancer has been reignited with the advancements in scientific knowledge and technology. We now possess tools that enable us to develop more targeted and effective viruses.14 Examples of oncolytic viruses studied to date include adenovirus, herpes simplex virus (HSV), measles virus, vesicular stomatitis virus (VSV), and vaccinia virus (VACV), among others. The ultimate goal of replication-competent anticancerous viral therapy is to produce a safe and effective therapeutic index with minimal toxicity and side effects.14

In addition to their oncotropic and oncolytic effects, advantages of using replication-selective oncolytic viruses for transgene delivery are several.15 In addition to their oncolytic capabilities,

replicating viruses can deliver therapeutic transgenes to image and enhance the probability of tumor eradication through multiple avenues. Replication-selective viral systems can employ endogenous viral gene expression control signals (promoter/enhancer, polyadenylation, and splice signals) for transgene expression. Eliminating the need for exogenous promoters often needed in replication-deficient systems and polyadenylation signals is an economical use of the often limited transgene capacity afforded a replicating viral agent. Using endogenous viral promoters may also allow more predictable and controlled transgene expression. Further, in contrast to foreign or exogenous promoters, the promoters of the replicating agent are optimized for expression in the infected cell. Viral gene expression is also highly regulated. Based on the expression of endogenous viral genes, it may be possible to predict the expression kinetics (timing and expression levels) of the transgene(s) carried by the replicating agent. Furthermore, when multiple transgenes are inserted into a single virus, their expression may be orchestrated to occur simultaneously or serially, at levels that will maximize their therapeutic benefits.

**NONINVASIVE IN VIVO MOLECULAR IMAGING OF REPLICATION-COMPETENT ONCOLYTIC VIRUSES**

Consequently, several strategies have been investigated for molecular imaging of viral replication within cancer (Figure 2). Molecular imaging is defined as the ability to visualize and quantitatively measure the function of biological and cellular processes in vivo. These are categorized broadly into optical imaging and deep-tissue imaging, and utilize several reporter genes such as fluorescence proteins, conditional enzymes, and membrane proteins and transporters. Various imaging methods are utilized for molecular imaging, including computed tomography (CT), magnetic resonance imaging (MRI), positron-emission tomography (PET), single photon-emission CT (SPECT), γ-scintigraphy, and photoacoustic imaging. In addition, several molecular probes are used for medical imaging applications, such as radioactive iodine species, technecium, and 18F-FIAU, which act as targeting moieties or signaling agents.

**Figure 1** Mechanism of oncolytic viral therapy. Oncolytic viruses specifically target cancer cells, replicate within them, eventually causing cell lysis and death, thereby releasing progenies that subsequently infect adjacent cancer cells.

**Figure 2** Overview of current oncolytic viruses genetically encoding reporter genes utilized for in vivo molecular imaging. (A) Optical imaging: (i) genes encoding for luciferases (Firefly and Renilla) mediated bioluminescence imaging via CCD cameras utilizing D-luciferin or coelenterazine substrates; (ii) genes encoding for fluorescent proteins (GFP and RFP) mediated fluorescence imaging via CCD cameras. Viruses encoding genes mediating both optical imaging modalities so far are vaccinia, adenovirus, HSV-1 and VSV. (B) Deep tissue imaging: (i) the enzyme reporter gene HSV1 thymidine kinase is activated by several 18F tagged substrates such as ganciclovir (18F-GCV) and may be imaged via PET and SPECT with viruses encoding this gene so far being a vaccinia and HSV-1 strain. Both reporter genes enable imaging of viral replication via PET, SPECT, and gamma scintigraphy; (ii) the somatostatin SSRT2 receptor gene facilitates uptake of somatostatin analogues usually radiolabelled with indium ([111In]-DTPA-D-Phe1-Octreotide) and may be imaged via PET, SPECT and gamma scintigraphy with viruses encoding this gene so far being only a vaccinia strain; (iv) a vaccinia virus has been genetically engineered to carry the gene encoding for melanin, which may be used as a contrast agent and facilitated imaging of viral replication via MRI and optoacoustic imaging.
Optical imaging

Optical detection methods mainly include fluorescence, such as green fluorescent protein (GFP), enhanced GFP (eGFP), and red fluorescent protein (RFP), and bioluminescence imaging (BLI), which utilizes luciferases. Optical detection methods have the advantage of short acquisition times (for fluorescence imaging a few milliseconds to several seconds, for bioluminescence a few seconds to several minutes) and high spatial resolution. The major disadvantage of optical imaging is its inability to perform deep-tissue imaging due to autofluorescence, light scattering, and the opacity of tissues below 600 nm due to absorbance of light by hemoglobin. Nevertheless, optical imaging in preclinical tests remains a very important tool to follow the distribution of oncolytic viruses.

Fluorescence. The most widely used reporter protein is GFP, and most of the GFP variants are derived from the jellyfish Aequorea victoria. Many synthetic variants, including an eGFP, have been developed for improving the stability and brightness of fluorescence without altering their fluorescence or the function of fusion protein. In vivo molecular imaging of fluorescent proteins is usually achieved with special adapted charged-couple device cameras to detect fluorescence.

Several virus strains have been equipped with genes encoding fluorescent proteins such as GFPs. Moreover, a GFP-encoding vaccinia virus strain (GLV-1h68) is currently in phase 1 and 2 clinical trials, in which GFP is being investigated for the confirmation of virus colonization of near-surface tumors and metastases. A number of viruses encoding RFPs have also been developed. For example, a VACV encoding for RFP has been shown to regress xenograft and syngeneic models of colorectal peritoneal carcinomatosis.

Bioluminescence. BLI is a very effective technique for use in small animal experimental models. It relies on the detection of very weak, visible light emitted by the oxidation of D-luciferin produced by the luciferase reporter gene in the presence of oxygen and ATP. Bioluminescence systems depend on the delivery of a specific substrate to the reporter expressing cells and the presence of oxygen. Bioluminescence reporter genes have been more widely used than fluorescence reporter genes for whole-body imaging due to the advantages of higher sensitivity and lower background luminescence. However, a major disadvantage of BLI is its low spatial resolution, and thus its use is limited in larger subjects, and it thus remains experimental.

The use of BLI in several virus strains has been equipped with genes encoding luciferases and bioluminescence imaging (BLI), which utilizes luciferases. Bioluminescence systems depend on the detection of very weak, visible light emitted by the oxidation of D-luciferin produced by the luciferase reporter gene in the presence of oxygen and ATP. Bioluminescence reporter genes have been more widely used than fluorescence reporter genes for whole-body imaging due to the advantages of higher sensitivity and lower background luminescence. However, a major disadvantage of BLI is its low spatial resolution, and thus its use is limited in larger subjects, and it thus remains experimental.

Deep-tissue imaging modalities

To date, three types of deep-tissue reporter genes have been explored with oncolytic viral therapies, those encoding for: enzymes (e.g., herpes simplex virus-thymidine kinase (HSV1-tk)), contrast agents (melanin), and receptors (such as somatostatin receptor) or synerporter/transport proteins (hNET, hNIS). The deep-tissue imaging methods have been explored with oncolytic viral therapies utilizing instrumentation such as PET, SPECT, and CT-scintigraphy, which have also been combined with CT for additional anatomic correlation. SPECT technology detects individual photons emitted by radioisotopes such as iodine-123 (123I) or 99m-technetium pertechnetate (99mTcO4). PET devices detect the gamma rays produced when positrons emitted from the radioisotope collide with local neighboring electrons. Despite their relatively limited spatial resolution (3–5 mm for PET and 8–10 mm for SPECT), both imaging modalities provide molecular and functional information with a high sensitivity, especially when compared with optical imaging. This high degree of sensitivity may allow the use of relatively weak promoters and the imaging of relatively low levels of gene expression. Comparatively, PET provides higher sensitivity than SPECT. The repeatability, quantifiability, and high sensitivity of deep-tissue reporter gene systems may lead to rapid advancements in our understanding of oncolytic viral therapies. Consequently, PET and SPECT currently offer the greatest potential for translation to clinical use.
increasing at 48 hours compared with that at 8 hours after viral injection, demonstrating that PET scanning can detect changes in TK activity resulting from local viral proliferation.

Contrast agents

Melanin. A recent study by Stritzker et al.43 explored the use of a VACV encoding for melanin production. The oncolytic virus-mediated production of melanin and its optical absorption in the near-IR spectrum enabled the imaging of A549 tumors and metastases via utilization of MRI and MSPT. The ubiquitous presence of melanin in all kingdoms of life suggests that introduction of melanin synthesis as a diagnostic/theranostic marker is possible in most species.

Receptors

Human somatostatin receptor 2 (hSSRT2). The SSTR2 is targeted by the high-affinity synthetic peptide pentetreotide, which is commonly used for receptor imaging after being radiolabeled with indium-111 (111In)44. This receptor is normally expressed in human kidney cells and neuroendocrine tumors, and gene therapy approaches to deliver the SSTR2 to tumors have also been attempted using adenoviral vectors.44,45 In a study by McCart et al.,46 nude mice bearing subcutaneous murine colon CA xenografts were injected intraperitoneally with an SSTR2-expressing VACV or control and imaged 6 days later with 111In-pentetreotide-mediated SPECT. Tumors infected with the SSTR2-expressing VACV accumulated higher concentrations of radioactivity compared with tumors in animals receiving the control virus. Further, the SSTR2-infected tumors were visible on imaging 6 days after VACV injection and could be visualized for up to 3 weeks post viral injection using repeat radiotracer injections. A limitation of the SSTR2 receptor is that radiotracers for SSTR2 require prior radiolabeling for the accumulation of radioprobes. Furthermore, unlike transporters such as the human norepinephrin transporter (hNET) and the human sodium iodide symporter (hNIS), SSTR2 is a receptor that usually has a 1:1 binding relationship with radiolabeled ligands and is therefore not capable of providing significant amplification through transport-mediated concentrative intracellular accumulation of substrate.

Human norepinephrin transporter (hNET). Another deep-tissue reporter gene investigated in oncolytic viral strains is the hNET. hNET is a cell-surface human protein, which belongs to a family of Na+/Cl-dependent transporters that contain multiple transmembrane domains and mediates the transport of norepinephrine, dopamine, and epinephrine across the cell membrane. It can mediate molecular imaging via SPECT or PET using the radiotracer metaiodobenzylguanidine (MIBG).47,48 The use of the hNET–MIBG reporter gene investigated in oncolytic viral strains is the hNET. hNET is a human Na+/Cl-dependent transporter that contains multiple transmembrane domains and mediates the transport of norepinephrine, dopamine, and epinephrine across the cell membrane. It can mediate molecular imaging via SPECT or PET using the radiotracer metaiodobenzylguanidine (MIBG).47,48 The use of the hNET–MIBG reporter gene investigated in oncolytic viral strains is the hNET. hNET is a cell-surface human protein, which belongs to a family of Na+/Cl-dependent transporters that contain multiple transmembrane domains and mediates the transport of norepinephrine, dopamine, and epinephrine across the cell membrane. It can mediate molecular imaging via SPECT or PET using the radiotracer metaiodobenzylguanidine (MIBG).47,48 The use of the hNET–MIBG reporter gene investigated in oncolytic viral strains is the hNET. hNET is a cell-surface human protein, which belongs to a family of Na+/Cl-dependent transporters that contain multiple transmembrane domains and mediates the transport of norepinephrine, dopamine, and epinephrine across the cell membrane. It can mediate molecular imaging via SPECT or PET using the radiotracer metaiodobenzylguanidine (MIBG).47,48

Chen et al.49 were the first to report on an oncolytic virus encoding for hNET, GLV-1h99, a derivative of VACV GLV-1h68 also encoding for GFP and RLuc. The hNET protein did not hinder viral replication and in vitro or in vivo treatment efficacy, and was expressed at high levels on the membranes of infected cells. GLV-1h99-mediated expression of hNET resulted in specific uptake of the radiotracer 123I-MIBG. In mice, GLV-1h99-infected pancreatic tumors were readily imaged by PET using 124I–MIBG. This virus was further investigated by Brader et al.50 for the imaging of an orthotopic mouse model of human malignant mesothelioma using both 124I–MIBG-mediated SPECT imaging and 124I–MIBG-mediated PET imaging. Another group investigated the use of the hNET gene utilizing an oncolytic herpes virus, but did not investigate its use for imaging.51 A limitation of the hNET symporter is the requirement for MIBG for radiotracer labeling. The question then remained: is there a potential deep-tissue imaging reporter gene of human origin, which facilitates concentrative intracellular uptake of carrier-free radioprobes, which can facilitate high-resolution PET imaging? This led to the interest in hNIS.

Human sodium iodide symporter (hNIS). This hNIS is an intrinsic plasma membrane protein, which mediates the active transport and concentration of iodide in the thyroid gland cells and some extra thyroidal tissues, in particular, the lactating mammary gland.52 Discovery and cloning of the rat NIS, by Carrasco and colleagues,53 and of the human NIS, by Jhiang and colleagues,54 mediating iodide uptake opened an exciting and extensive new field of research, including exploring the pathophysiological implications of NIS in thyroid disease, the therapeutic potential of the gene, and its imaging and diagnostic potentials. hNIS gene transfer via viral vector may allow infected tumor cells to concentrate several easily attainable, commercially available, and relatively inexpensive, carrier-free radioisotopes such as 123I, 124I, 125I, 131I, 99mTcO4−, rhenium, and astatine for noninvasive imaging of NIS expression, all of which have long been approved for human use. hNIS has also been shown to be comparable to the commonly used HSV1-tk reporter gene55 and correlated with 99mTcO4.57 This can be very useful for viral distribution with SPECT or PET scanning during and after viral therapy, and may allow for correlation with efficacy and toxicity during clinical trials, thus offering potential clinical translation of this dual therapy.

The oncolytic viruses that have been investigated so far in relation to hNIS are adenoviruses, measles, vesicular stomatitis, vaccinia, and most recently a HSV. Merron et al.58 were the first to insert the hNIS reporter gene in a wild-type replicating oncolytic adenovirus (AdIP1) and in an adenovirus in which a promoter from the human telomerase gene (RNA component) drives E1 expression (AdAM6). The virus-induced functional hNIS expression and replication in cell culture and kinetics of spread of the different viruses in colorectal tumor xenografts were visualized in vivo using 99mTcO4−-mediated SPECT. Hakkarainen et al.59 created the adenovirus Ad5/3-Δ24-hNIS, a Rb-p16 pathway-selective infectivity-enhanced oncolytic adenovirus encoding hNIS. Ad5/3-Δ24-hNIS replication effectively repressed prostate cancer PC-3MM2 tumors with viral replication visualized via 123I-mediated γ-scintigraphy, and this virus is now in clinical trials.60 Another replication-competent oncolytic virus armed with two suicide genes and the NIS gene, Ad5-γCD/mutTK(SR39)rep-hNIS, was injected into contralateral lobes of the dog prostate and hNIS activity was monitored in live animals using γ-scintigraphy, allowing for dynamic monitoring of reporter gene expression within the prostate as well as biodistribution throughout the body.60 Several other adenoviruses, which carry the hNIS gene under several promoters in various cancers, have also been constructed using either intratumoral, intravenous, or intraperitoneal virus administration. A significant disadvantage was the reduced replication capacity of adenovirus.51-54

Several groups have also attempted hNIS transfer via oncolytic measles vectors. Dingli et al.65 were the first to show the noninvasive imaging and therapy potential of a measles virus encoding for hNIS (MV-NIS) by 123I-γ-scintigraphy imaging of the intratumoral spread of various multiple myeloma xenografts. Hasegawa et al.66 tested MV-NIS in combination with another viral construct, MV-CEA, to treat ovarian cancer SKOV3ip.1 xenografts. MV-NIS propagation was...
Molecular imaging of oncolytic viral therapy
D Haddad and Y Fong

again mapped by serial radioiodine imaging via gamma scanner by systemic injection of $^{99m}$TcO$_4$. However, γ-scintigraphy was considerably less sensitive than the plasma CEA marker for monitoring virus infection. Further, Liu et al.$^{67}$ demonstrated that antitumor activity of MV-NIS was evident only in measles naive mice-bearing disseminated myeloma, and not in passively immunized mice, which may limit the clinical application of this virus. Several other studies have investigated the use of measles virus carrying the NIS gene.$^{68-70}$
In mice with established subcutaneous STG1 melanoma tumors, virus replication and spread of a vesicular stomatitis virus, VSV (51)-NIS, were also monitored noninvasively by serial \( ^{125}\text{I}\gamma\)-scintigraphy imaging after systemic or intratumoral injection. Dosimetry calculations based on these images pointed to the feasibility of combination radiovirotherapy with VSV(51)-NIS and \( ^{131}\text{I} \).

Our lab was the first to investigate a VACV carrying the hNIS, GLV-1h153, which is also a derivative of GLV-1h68.\(^7\) The virus also encoded for a GFP and the RLuc gene, and was found to be successful in the fluorescent, bioluminescent, and deep-tissue image monitoring of viral replication and therapy (Figure 3).\(^2,7\) Moreover, GLV-1h153 successfully regressed several tumor types in preclinical models including pancreatic cancer, triple-negative breast cancer, gastric cancer, and malignant pleural mesothelioma.\(^7,8,24\)

**CLINICAL TRIALS WITH OVS ENCODING FOR REPORTER GENES**

Preclinical imaging and therapy success with oncolytic viruses and reporter genes have led to several completed and ongoing clinical trials (Table 1).\(^3\) The clinical application of gene delivery will require the generation and investigation of safe and efficient gene-delivery systems, as well as the ability for systemic administration and regulated gene expression. Only a very small number of gene expression imaging studies have been carried out to date in humans utilizing oncolytic viral therapies.

The NIS-based strategy was the first approach. Men with clinically localized prostate cancer were administered an intra-prostatic injection of the replication-competent adenovirus AdS-yCD/utTKSR39rep-hNIS for the imaging of prostate cancer.\(^7\) NIS gene expression was imaged noninvasively by the uptake of \( ^{99m}\text{TcO}_4 \) in infected cells using SPECT. Therapy was shown to be safe with 98% of the adverse events of grade 1 or 2. Enhanced radio-uptake was detected in the prostate in seven of nine patients. Further, the expression was monitored and found to increase to around 18% of the total prostate volume following injection of virus, which peaked 1–2 days post adenovirus injection and was detectable in the prostate for up to 7 days. No evidence of extra-prostatic dissemination of the adenovirus was evident via SPECT imaging. The results demonstrated for the first time in humans the noninvasive imaging capability of hNIS utilizing an oncolytic viral vector.\(^9\) Other trials are also underway investigating the potential of AdS-CMV-NIS for gene therapy and combination with radioactive iodine in treating patients with locally recurrent radiotherapy-resistant prostate cancer that did and recurrent cervical cancer.\(^3\)

Several clinical trials have also been carried out with MV-NIS. The first was a dose-escalation phase 1 trial of MV-NIS when given with or without cyclophosphamide in treating patients with recurrent or refractory multiple myeloma.\(^2\) The time course of viral gene expression and viral elimination, as well as the biodistribution of virally infected cells at various time points after treatment with these regimens using \( ^{125}\text{I}\gamma\)-scintigraphy imaging, will also be determined. In addition, several other groups are recruiting patients for clinical trials in order to investigate the therapeutic effects of various MV-NIS with various cancers alongside SPECT/CT imaging of the course of viral gene expression, elimination, and biodistribution at various time points after treatment. The first phase 2 clinical trial utilizing oncolytic viruses and NIS will begin recruiting utilizing MV-NIS for multiple myeloma.

**THERAPEUTIC POTENTIAL WITH REPORTER GENES**

Although self-replicating virotherapy encoding reporter genes has shown great promise for treating cancer and for the noninvasive molecular imaging and monitoring of viral therapy, the additive or synergistic effects by combining targeted therapeutic systemic therapies, including prodrugs and radiotherapy, may aid in the elimination of tumors and virus-resistant tumors.

For example, the produg acycloguanosine, such as ganciclovir, is phosphorylated by the HSV1-tk transgene (and only poorly by the endogenous tk). This phosphorylation converts the membrane-permeable produg into a polar product, which is trapped in the cell. This phosphorylated product is then incorporated into the DNA where it acts as a chain terminator, inducing cell death. Apart from the transduced cancer cells, neighboring, nontransfected cells can also be killed through a mechanism referred to as the bystander effect.

Oncolytic viruses encoding transporter genes such as hNIS have also been found to have a synergistic antitumor effect when combined with ionizing radiation, such as \( ^{131}\text{I} \).\(^8,9\) One mechanism for such synergy appears to be radiation-induced upregulation of certain cellular DNA repair genes that result in promoting viral replication.\(^8,3,10\) Furthermore, a bystander effect may be possible as \( ^{131}\text{I} \) undergoes \( \alpha \)–particle decay with a path length of 0.2–2.4 mm.\(^1,5\) It is important to note that \( ^{131}\text{I} \) is already approved in patients for multiple ailments, including thyroid cancers and palliation of bone metastasis, and is found to be safe with relatively few side effects.\(^8,6\) In addition, \( ^{131}\text{I} \) is not a gene therapy and thus involves less risk and complications as compared with gene therapy of cancer. If additive or synergistic effects are found, patients may be more safely treated with combinations of lower doses of virus and radioiodine.

The application of carrier-free radioiodine would thus be extended, and the extensive experience with radioiodine in thyroid cancer management will undoubtedly be helpful in the treatment of other NIS-transfected tumors. Our lab demonstrated an enhanced effect of oncolytic viral therapy with GLV-1h153 when combined with radiotherapy \( ^{131}\text{I} \) in both pancreatic and breast cancer xenografts. The VACV encoding the gene for SSTR2 combined with the radiotherapeutic \( ^{125}\text{I-in-DOTATOC} \) was also shown to be more effective than either alone at decreasing the growth rate of human embryonic kidney HEK-293 cells or colorectal MC-38 cells in monolayer.\(^4,5\) Furthermore, AdS/3-\( \Delta \)24-hNIS with radioiodide was significantly more effective than virus alone in mice with prostate cancer xenografts.

The contrast agent melanin may facilitate near-IR–assisted thermotherapy in addition to oncolytic virotherapy.\(^6,3\) A near-IR laser was utilized to specifically transfer energy to melanin-induced cells, with the transferred energy consequently converted to thermal energy, eventually heating the melanin-producing cells and cells in their vicinity to temperatures causing protein denaturation and cell death, therefore enabling thermotherapy. Stritzker et al. demonstrated that aliquots containing cells infected with VACV-encoding melanin achieved a higher temperature exposed to laser light, with near-complete kill of all cells within those aliquots as compared with mock infected cells. They also demonstrated that lung cancer xenografts on tumor-bearing mice treated with the melanin-inducing VACV had significantly enhanced regression when using...
a single 2-minute laser treatment, compared with tumors that were not exposed to the laser light, demonstrating an additive effect.

CONCLUSIONS

Noninvasive in vivo molecular imaging of oncolytic viral therapy has experienced a significant surge in preclinical and clinical studies, which may eventually aid in the design and improvement of early cancer detection, patient-specific treatment selection, targeted delivery, and therapy-specific monitoring of gene therapy, in order to better treat and cure diseases with high mortality. Preclinical research has resulted in the identification of a large number of reporter genes, many of which have already been utilized with several strains of oncolytic viruses, in addition to the development of novel molecular imaging contrast agents and imaging devices, hardwares, and software technologies. The capacity to quantitatively and precisely visualize and monitor the in vivo regulation of viral replication and biodistribution and kinetics of gene expression may also lead to advances in the safety and efficacy of oncolytic viruses as vectors for gene therapy. Among the safety issues, cell-specific targeting is an important consideration of all cancer gene therapy trials. With preclinical success and further clinical trials, molecular imaging of oncolytic viral gene therapies will likely play an increasing role in the clinical treatment of cancer. Most current applications use PET and SPECT imaging, and other molecular imaging techniques, including MRI/MRS, optical (Raman), molecular US, and photoacoustic tomography, warrant further investigation.
