Abstract

The coherence properties of phase fluctuating Bose-Einstein condensates are studied both theoretically and experimentally. We derive a general expression for the $N$-particle correlation function of a condensed Bose gas in a highly elongated trapping potential. The second order correlation function is analyzed in detail and an interferometric method to directly measure it is discussed and experimentally implemented. Using a Bragg diffraction interferometer, we measure intensity correlations in the interference pattern generated by two spatially displaced copies of a parent condensate. Our experiment demonstrates how to characterize the second order correlation function of a highly elongated condensate and to measure its phase coherence length.

I. INTRODUCTION

Among the various topics related to the exciting field of Bose-Einstein condensation (BEC)\cite{1}, the analysis of coherence properties of degenerate Bose gases has attracted major interest. Coherence plays a key role in the understanding of the fundamentals of BEC, and has a crucial importance for many promising BEC applications, such as matter wave interferometry, guided atomic beams, and atom lasers. The coherent character of trapped 3D condensates well below the BEC transition temperature $T_c$ has been confirmed by several experiments, using interferometric\cite{2,3} and spectroscopic methods\cite{4}.

However, recent theoretical and experimental developments have shown that phase coherence is far from being an obvious property of BEC. In particular, a phase fluctuating BEC at equilibrium has been theoretically predicted in one-dimensional\cite{5}, two-dimensional\cite{6,7}, and even in highly elongated, but still three-dimensional\cite{8} trapped Bose gases. Interestingly, in these cases the density distribution does not differ from the usual BEC profile, since density fluctuations are largely suppressed by the repulsive mean-field potential. These systems are commonly called quasicondensates. Phase fluctuations can be induced either by quantum\cite{9} or by thermal fluctuations\cite{10}. For typical experimental temperatures quantum phase fluctuations can safely be neglected as long as the system remains in the weakly-interacting regime\cite{11}. The amplitude of phase fluctuations, therefore, depends strongly on temperature and trapping geometry. In this sense, a nearly phase coherent BEC in a highly elongated trap can only be achieved far below $T_c$, imposing severe limitations on experiments in constrained geometries. Phase fluctuating BECs have been the subject of recent theoretical efforts, including the development of a modified mean-field theory valid in all dimensions and all temperatures below the critical point\cite{12,13}, the analysis of dynamic correlation functions\cite{14}, and the extension of Bogoliubov theory to low-dimensional degenerate Bose gases\cite{15}.

The phase fluctuating nature of highly elongated BECs was first experimentally demonstrated in Ref.\cite{16}. During the ballistic expansion, phase fluctuations transform into density modulations. The appearance of phase fluctuations and their statistic nature were studied and the dependence of their average value on experimental parameters was characterized\cite{16,17}. Moreover, the results obtained from measurements of the energy released during the expansion confirmed the absence of density fluctuations in the trapped cloud\cite{18,19}. 
Recently, the physics of quasicondensates has been studied by means of Bragg spectroscopy, showing that the existence of phase fluctuations leads to an observable broadening of the momentum distribution \[19, 20\]. A further experiment has analyzed the phase coherence length of non-equilibrium BECs by means of a condensate-focusing technique \[21\].

In this paper, we present the theoretical foundation of our studies on coherence properties of phase fluctuating condensates. We analyze the behavior of the second order correlation function for our experimental conditions and provide a detailed discussion of the experimental technique used in Ref. \[22\] to measure it. This technique is based on the analysis of the density correlations in the interference pattern generated by a matter wave Bragg interferometer. In analogy to the original Hanbury-Brown and Twiss experiment \[23, 24\], our method is used to extract the phase coherence length of the degenerate Bose gas from density correlation measurements.

This paper is organized as follows: In Sec. II, we briefly review the theory of phase fluctuating Bose-Einstein condensates in 3D elongated traps \[8\] and analyze the evolution of the phase pattern during the ballistic expansion. The knowledge of the free dynamics of the phase is important to closely model the BEC evolution during the measurement process. In Sec. III, we study the coherence properties of the condensate and derive a general expression for the \(N\)-particle correlation function of highly elongated 3D BECs. In Sec. IV, the experimental technique used to measure the second-order correlation function and the phase coherence length of the condensate is reviewed in detail.

II. PHASE FLUCTUATING CONDENSATES

In this section, we present the phase operator of a highly elongated condensate \[8\] and develop an analytic description of the ballistic expansion of the fluctuating phase pattern. These results, when combined with the free evolution of density modulations presented in \[16, 17\], provide a full understanding of the order parameter dynamics during the time-of-flight.
A. Phase operator

In the following, we consider a cylindrically symmetric condensate in the Thomas-Fermi regime, where the repulsive mean-field interaction exceeds the radial ($\bar{h}\omega_\rho$) and the axial ($\bar{h}\omega_z$) trap energies. At $T = 0$, the density profile has the well-known shape $n_0(\rho, z) = n_{0m}(1 - \rho^2/R^2 - z^2/L^2)$, where $n_{0m} = \mu/g$ denotes the maximum density of the condensate, $\mu$ is the chemical potential, $g = 4\pi\hbar^2 a/m$ the interaction constant, $m$ the atomic mass, and $a > 0$ the scattering length. Under the condition $\omega_\rho \gg \omega_z$, the radial size of the condensate, given by the Thomas-Fermi radius $R = (2\mu/m\omega_\rho^2)^{1/2}$, is much smaller than the axial size, which corresponds to the Thomas-Fermi length $L = (2\mu/m\omega_z^2)^{1/2}$.

Due to the repulsive mean-field energy, density fluctuations are strongly suppressed in a trapped BEC. Therefore, the field operator describing the condensate can be written in the form $\hat{\psi}(\mathbf{r}) = \sqrt{n_0(\mathbf{r})}\exp(i\hat{\phi}(\mathbf{r}))$, where the phase operator is defined by (see e.g. Ref. [25])

$$\hat{\phi}(\mathbf{r}) = \left[4n_0(\mathbf{r})\right]^{-1/2}\sum_{j=1}^{\infty} f_j^+(\mathbf{r})\hat{a}_j + \text{h.c.}.$$  \hspace{1cm} (1)

Here $\hat{a}_j$ represents the annihilation operator of the quasiparticle excitation with quantum number $j$ and energy $\epsilon_j$; $f_j^+ = u_j + v_j$ is the sum of the excitation wavefunctions $u_j$ and $v_j$, obtained from the corresponding Bogoliubov-de Gennes (BdG) equations. The low-energy axial modes, which are responsible for the long wavelength axial phase fluctuations, have the energy spectrum $\epsilon_j = \bar{h}\omega_z\sqrt{j(j+3)/4}$ [26]. The wavefunctions $f_j^+$ of these quasiparticle modes have the form [8]

$$f_j^+(\mathbf{r}) = \sqrt{\frac{(j+2)(2j+3)gn_0(\mathbf{r})}{4\pi(j+1)R^2L\epsilon_j}}P_{j}^{(1,1)}\left(\frac{z}{L}\right),$$  \hspace{1cm} (2)

where $P_{j}^{(1,1)}$ are Jacobi polynomials. Equations (1) and (2) show that the phase operator only depends on the axial coordinate $z$. In sec. III, we analyze the coherence properties of the condensate by studying the correlation functions of the operator $\hat{\psi}(\mathbf{r})$.

B. Evolution of the phase fluctuating pattern

Starting from the results presented in Refs. [16, 17], we analyze the evolution of phase fluctuations during the free expansion of the degenerate Bose gas. Since the trap is highly elongated, we can assume the condensate as an infinite cylinder, and use the local density
approximation. The time-of-flight dynamics of the order parameter is described by the scaling law \[27, 28\]
\[
\psi(\rho, z, t) = \frac{\kappa(\rho, z, t)}{\lambda_\rho(t)} e^{i \frac{m \lambda_\rho^2}{2 \hbar} \rho^2} e^{-i \tilde{\tau} \frac{\rho}{\lambda_\rho(t)}},
\]
where \( (m \lambda_\rho^2/2\hbar \lambda_\rho) \rho^2 \) is the quadratic phase associated with the expansion dynamics, \( \lambda_\rho^2(t) = 1 + \omega_\rho^2 t^2 \) is the scaling coefficient, \( \tilde{t} = \int^t dt'/\lambda_\rho(t')^2 \) is the re-scaled time, and \( \rho = \rho/\lambda_\rho(t) \) is the re-scaled radial coordinate. Let \( \kappa_0 = \sqrt{\kappa_1} \) be the solution of the following equation
\[
\left[ -\frac{\hbar^2}{2m} \nabla_\rho^2 + \frac{m \omega_\rho^2}{2} \rho^2 + g|\kappa_0|^2 - \mu \right] \kappa_0 = 0.
\]
If we define \( \kappa = \sqrt{n} \exp(i \phi) \), with \( n = n_0 + \delta n \), and substitute the scaling law of Eq. (3) into the corresponding Gross-Pitaevskii equation (GPE), after linearizing in \( \delta n \) and \( \phi \) we obtain:
\[
\frac{\partial (\delta n)}{\partial t} = \frac{\xi \phi}{\lambda_\rho^2(t)} - \frac{\hbar}{m} \frac{\partial^2}{\partial z^2} (n_0 \phi),
\]
(5)
\[
\frac{\partial (n_0 \phi)}{\partial t} = -\frac{\xi \delta n/n_0}{4 \lambda_\rho^2(t)} + \frac{\hbar}{4m} \frac{\partial^2}{\partial z^2} (\delta n) - \frac{g n_0}{h \lambda_\rho^2(t)} (\delta n),
\]
(6)
where \( \xi = -(\hbar/m) [n_0 \nabla_\rho^2 + \nabla_\rho n_0 \nabla_\rho] \). The first term on the right hand side of Eq. (6) can be neglected in the Thomas-Fermi regime. Following Ref. \[26\], we average over the radial coordinates. Let \( n_I \) be the radially-integrated unperturbed density, and \( \delta n_I \) the radially-integrated density fluctuations. From Eq. (6) we obtain:
\[
\phi(\bar{z}, \tau) = \phi(\bar{z}, 0) + \frac{1}{8 \lambda^2 \zeta} \frac{\partial^2}{\partial \bar{z}^2} \left[ \int^\tau \frac{\delta n_I(\bar{z}, \tau')}{n_I(\bar{z}, \tau')} d\tau' \right] - \frac{\zeta}{2} \int^\tau 1 \frac{\delta n_I(\bar{z}, \tau')}{\lambda^2(\tau')} n_I(\bar{z}, \tau') d\tau',
\]
(7)
with \( \tau = \omega_\rho t, \bar{z} = z/L, \zeta = \mu/h \omega_\rho, \) and \( \lambda = \omega_\rho/\omega_z \). Equation (7) can be evaluated from the known expression \[16\]
\[
\frac{\delta n_I(\bar{z}, \tau)}{n_I(\bar{z}, \tau)} = \sum_j c_j P_j^{(1,1)}(\bar{z}) \sin \left( \frac{a_j \tau}{1 - \bar{z}^2} \right) \tau^{-b_j},
\]
(8)
where \( b_j = (e_j/h \omega_\rho)^2, a_j = b_j/\zeta \) and
\[
c_j = \left[ \frac{(j + 2)(2j + 3)g}{4\pi R^2 Le_j(j + 1)} \right]^{1/2} \left( \frac{\alpha_j + \alpha_j^*}{2} \right).
\]
(9)
\( \alpha_j \) and \( \alpha_j^* \) are random variables with a zero mean value and \( \langle |\alpha_j|^2 \rangle = N_j \), \( N_j \) being the occupation of the quasiparticle mode \( j \). Near the trap center, \( \delta n_I/n_I \sim \)
\[ \sum_j c_j P_j^{(1,1)}(\tilde{z}) \sin(a_j \tau) \tau^{-b_j}, \text{ and hence} \]
\[ \phi(\tilde{z}, \tau) = \phi(\tilde{z}, 0) + \sum_j c_j \left\{ \frac{(j+3)(j+4)}{32 \zeta \lambda^2} P_j^{(3,3)}(\tilde{z}) \int_0^\tau d\tau' \sin(a_j \tau')(\tau')^{-b_j} \right\} \]
\[ - \frac{\zeta}{2} P_j^{(1,1)}(\tilde{z}) \int_0^\tau d\tau' \frac{\sin(a_j \tau')(\tau')^{-b_j}}{1 + \tau'^2} \right\}. \] (10)

For large \( \lambda \) and sufficiently short times-of-flight, the significant contribution to the phase fluctuations is due to the modes \( j \) such that \( \tau << \lambda^2 \zeta / [j(j+3)/4] \), and \( b_j = j(j+3)/4\lambda^2 \ll 1 \). Then, using Eq. (11) for \( \phi(\tilde{z}, 0) \), we obtain:
\[ \phi(\tilde{z}, \tau) \simeq \sum_j c_j \left\{ 1 - \frac{1}{2} \arctan(\tau) \frac{j(j+3)}{4\lambda^2} \right\} P_j^{(1,1)}(\tilde{z}). \] (11)

The second term in the brackets is the correction to the phase contribution of the \( j \)-th mode due to the ballistic expansion. For typical times-of-flight (tens of milliseconds), this correction term is very small (\( \simeq 10^{-5} \)) and the phase pattern can be assumed as completely frozen. Using Eq. (10), we have verified that, for our typical experimental parameters (see Sec. IV-C), the phase change due to the free evolution of the condensate is less than \( \pi/10 \).

III. CORRELATION FUNCTIONS OF A PHASE FLUCTUATING CONDENSATE

The coherence properties of a condensate are described by the correlation functions of the field operator \( \hat{\psi} \). The importance of correlation functions becomes clear if we consider that most experimental signals can be modelled by using this formalism. For example, the first and second order correlation functions, describing the single-particle and two-particle correlation properties of the system, are connected to the visibility of fringes in an interference experiment and to the two-body collision rate in the condensate, respectively.

As discussed in Ref. [8], the single-particle correlation function of a highly elongated degenerate Bose gas can be expressed in terms of the mean square fluctuations of the phase:
\[ \langle \hat{\psi}^\dagger(\mathbf{r}_1) \hat{\psi}(\mathbf{r}_2) \rangle = \sqrt{n_0(\mathbf{r}_1)n_0(\mathbf{r}_2)} \exp \left\{ -\langle (\delta \hat{\phi}(\mathbf{r}_1, \mathbf{r}_2))^2 \rangle / 2 \right\}, \] (12)
where \( \delta \hat{\phi}(\mathbf{r}_1, \mathbf{r}_2) = \hat{\phi}(\mathbf{r}_1) - \hat{\phi}(\mathbf{r}_2) \) depends directly on the phase operator \( \hat{\phi} \) given in Eqs. (1). At equilibrium, the population of the \( j \)-th quasiparticle mode, \( \langle \hat{a}_j^\dagger \hat{a}_j \rangle \), is a random variable
with mean value \( N_j \), given by the Bose-Einstein distribution function. The appearance of phase fluctuations is a stochastic process governed by the temperature \( T \) of the system. Since individual realizations are not predictable, we average over an ensemble of identically prepared condensates in thermal equilibrium at temperature \( T \). This average is indicated by \( \langle . . . \rangle_T \). When \( k_B T \gg \hbar \omega_z \) \((k_B \) is the Boltzmann constant), the population of the \( j \)-th mode is \( N_j \sim k_B T/\epsilon_j \), and the thermal average of the mean square fluctuations of the phase becomes

\[
\langle [\delta \hat{\phi}(z_1, z_2)]^2 \rangle_T = \delta_L^2(T) f^{(1)}(z_1/L, z_2/L), \tag{13}
\]

where

\[
\delta_L^2(T) = \frac{32\mu k_B T}{15N_0(\hbar \omega_z)^2}, \tag{14}
\]

and

\[
f^{(1)}(z_1/L, z_2/L) = \frac{1}{8} \sum_{j=1}^{\infty} \frac{(j+2)(2j+3)}{j(j+1)(j+3)} \left[ P_{j(1,1)}^{(1,1)} \left( \frac{z_1}{L} \right) - P_{j(1,1)}^{(1,1)} \left( \frac{z_2}{L} \right) \right]^2, \tag{15}
\]

\( N_0 \) indicating the number of atoms in the condensate fraction. The first order correlation function of the degenerate Bose gas is defined by (see e.g. \[29\])

\[
g^{(1)}_T(r_1, r_2) = \frac{\langle \hat{\psi}^\dagger(r_1) \hat{\psi}(r_2) \rangle_T}{\langle \langle \hat{\psi}^\dagger(r_1) \hat{\psi}(r_1) \rangle_T \langle \hat{\psi}^\dagger(r_2) \hat{\psi}(r_2) \rangle_T \rangle^{1/2}}. \tag{16}
\]

According to Eqs. (12) and (13), this results in

\[
g^{(1)}_T(z_1, z_2) = \exp\{-\delta_L^2(T) f^{(1)}(z_1/L, z_2/L)/2\}. \tag{17}
\]

For \( |z_1|, |z_2| \ll L \), using the asymptotic expression of the Jacobi Polynomials [30], and summing over the different modes in the continuous limit, one obtains an approximated formula for the \( f^{(1)} \) function valid around the center of the condensate [8]:

\[
f^{(1)}(z_1/L, z_2/L) = |z_1 - z_2|/L. \tag{18}
\]

In that case,

\[
g^{(1)}_T(z_1, z_2) = \exp\{-\delta_L^2(T) |z_1 - z_2|/2L\}. \tag{19}
\]

This result suggests the introduction of the phase coherence length of the condensate

\[
L_\phi = \frac{L}{\delta_L^2(T)}, \tag{20}
\]

defined as the distance at which the first order correlation function decreases to \( 1/\sqrt{e} \). The approximate formula shown in Eq. (18) can be extended to describe the behavior of the \( f^{(1)} \)
function far from the center of the condensate. For $\delta^2 L(T) \gg 1$, the coherence length $L_\phi$ is small compared to the axial size $L$, and the system is well described by means of the local density approximation \[16, 17, 20\]. As pointed out in Ref. \[20\], this limit is equivalent to the use of the approximate formula for the Jacobi polynomials with large $j$ \[30\]. Equation (15) can thus be written in the form

$$f^{(1)}(z_1/L, z_2/L) = \frac{|z_1 - z_2|/L}{[1 - (z_1 + z_2)^2/(2L)^2]^2},$$

generalizing the result obtained in Eq. (18).

We use a similar approach to calculate the two-particle correlation function of the condensate. Introducing the operator $\delta^{(2)} (r_1, r_2, r_3, r_4) = \hat{\phi}(r_1) + \hat{\phi}(r_2) - \hat{\phi}(r_3) - \hat{\phi}(r_4)$, we obtain

$$\langle \hat{\psi}^\dagger(r_1) \hat{\psi}^\dagger(r_2) \hat{\psi}(r_3) \hat{\psi}(r_4) \rangle = \prod_{i=1}^{4} \sqrt{n_0(r_i)} \exp \left\{-\langle \delta^{(2)} \hat{\phi}(r_1, r_2, r_3, r_4) \rangle^2 \right\}.$$  \hspace{1cm} (22)

Using Eq. (11) for the phase operator, a straightforward calculation yields

$$\langle \delta^{(2)} \hat{\phi}(z_1, z_2, z_3, z_4) \rangle^2 = \sum_{j=1}^{\infty} \frac{(j + 2)(2j + 3)\mu}{15(j + 1)e_j N_0} N_j \times \left[ P^{(1,1)}_j \left( \frac{z_1}{L} \right) + P^{(1,1)}_j \left( \frac{z_2}{L} \right) - P^{(1,1)}_j \left( \frac{z_3}{L} \right) - P^{(1,1)}_j \left( \frac{z_4}{L} \right) \right]^2.$$  \hspace{1cm} (23)

In the limit $k_B T \gg \hbar \omega_z$, the thermal average of Eq. (23) gives

$$\langle \delta^{(2)} \hat{\phi}(z_1, z_2, z_3, z_4) \rangle_T = \delta^2 L(T) f^{(2)}(z_1/L, z_2/L, z_3/L, z_4/L),$$

where

$$f^{(2)}(z_1/L, z_2/L, z_3/L, z_4/L) = f^{(1)}(z_1/L, z_3/L) + f^{(1)}(z_2/L, z_4/L) - f^{(1)}(z_1/L, z_2/L) - f^{(1)}(z_3/L, z_4/L) + f^{(1)}(z_1/L, z_4/L) + f^{(1)}(z_2/L, z_3/L).$$

Thus, the two-particle correlation function can be expressed as a product of one-particle correlation functions. Equations (18) and (21) can be used to derive simplified expressions for the $f^{(2)}$ function, valid in the limit $|z_i| \ll L$ ($i = 1, \ldots, 4$) and in the local density approximation. Figure 1 shows the dependence of $f^{(2)}$ calculated in

$$\bar{z}_1 = \frac{d + s}{2}, \quad \bar{z}_2 = \frac{-d - s}{2}, \quad \bar{z}_3 = \frac{-d + s}{2}, \quad \bar{z}_4 = \frac{d - s}{2}$$

(26)
FIG. 1: $f^{(2)}(\bar{z}_1/L, \bar{z}_2/L, \bar{z}_3/L, \bar{z}_4/L)$ as a function of $s > 0$. The complete expression in Eq. (25) (solid line) is compared with the approximated formulas derived from Eqs. (18) and (21), valid in the condensate center (dotted line) and in the local density approximation (dashed line). The inset shows $f^{(2)}$ for different values of $d > 0$. as a function of $s > 0$. The full expression of $f^{(2)}$ can be compared with the two approximated formulas, the first valid in the condensate center, the second valid in the local density approximation. The inset of Fig. 1 shows the same curves for different values of $d > 0$. This choice of variables follows the particular experimental realization. In Sec. IV, we demonstrate how these curves can be measured in a matter wave interferometry experiment. There, $d$ is the displacement between the two interfering condensate copies, and $s$ is the separation between the positions in the interference pattern at which the particle densities are evaluated.

A qualitative understanding of the behavior shown in Fig. 1 is possible if we consider that

$$\langle [\delta \hat{\phi}(\bar{z}_1, \bar{z}_3)]^2 \rangle_T = \langle [\delta \hat{\phi}(\bar{z}_1, \bar{z}_3)]^2 \rangle_T + \langle [\delta \hat{\phi}(\bar{z}_2, \bar{z}_4)]^2 \rangle_T + 2\langle \delta \hat{\phi}(\bar{z}_1, \bar{z}_3)\delta \hat{\phi}(\bar{z}_2, \bar{z}_4) \rangle_T. \tag{27}$$

The first and the second term are the thermal averages of the operator $(\delta \hat{\phi})^2$ calculated in $(\bar{z}_1, \bar{z}_3)$ and in $(\bar{z}_2, \bar{z}_4)$; the last term is proportional to the correlation function of $\delta \hat{\phi}$ at the same coordinates. For a fixed displacement $d$, when the examined positions are close to the
condensate center \((d, s \ll L)\), the first two terms of Eq. (27) do not depend on the separation \(s\). However, as \(s\) rises from 0 to \(d\), the third term increases from \(-2\langle [\delta \tilde{\phi}(\bar{z}_1, \bar{z}_3)]^2 \rangle_T\) (complete anticorrelation) to its maximum value 0, resulting in an uncorrelated phase difference for every \(s \geq d\). In the interval \(0 \leq s \leq d\), the \(f^{(2)}\) function depends linearly on \(s\) with slope 2.

The second order correlation function is defined as
\[
g^{(2)}_T(r_1, r_2, r_3, r_4) = \frac{\langle \hat{\psi}^\dagger(r_1) \hat{\psi}^\dagger(r_2) \hat{\psi}(r_3) \hat{\psi}(r_4) \rangle_T}{\langle \langle \hat{\psi}^\dagger(r_1) \hat{\psi}(r_1) \rangle_T \ldots \langle \hat{\psi}^\dagger(r_4) \hat{\psi}(r_4) \rangle_T \rangle_{T}^{1/2}}. \tag{28}
\]
Substituting Eqs. (22) and (24) in Eq. (28), we obtain:
\[
g^{(2)}_T(z_1, z_2, z_3, z_4) = \exp\{-\delta_L^2(T)f^{(2)}(z_1/L, z_2/L, z_3/L, z_4/L)/2\}. \tag{29}
\]
Note that, due to the suppression of density modulations, the normalized density correlation function of the trapped condensate is constant: \(g^{(2)}_T(z_1, z_2, z_2, z_1) = 1\).

The calculation we have described for the second order correlation function can be extended to obtain a general expression for the \(N\)-th order correlation function. Defining the operator
\[
\delta^{(N)}\hat{\phi}(\{r_i\}_{i=1,\ldots,2N}) = \hat{\phi}(r_1) + \ldots + \hat{\phi}(r_N) - \hat{\phi}(r_{N+1}) - \ldots - \hat{\phi}(r_{2N}), \tag{30}
\]
the \(N\)-particle correlation function is given by
\[
\langle \hat{\psi}^\dagger(r_1) \ldots \hat{\psi}^\dagger(r_N) \hat{\psi}(r_{N+1}) \ldots \hat{\psi}(r_{2N}) \rangle = \prod_{i=1}^{N} \sqrt{n_0(r_i)} \exp \{-\langle \delta^{(N)}\hat{\phi}(\{r_i\}_{i=1,\ldots,2N}) \rangle_T^2/2\}. \tag{31}
\]
In general, the thermal average of the operator \((\delta^{(N)}\hat{\phi})^2\) can be written in the form
\[
\langle [\delta^{(N)}\hat{\phi}(\{r_i\}_{i=1,\ldots,2N})]^2 \rangle_T = \delta_L^2(T)f^{(N)}(\{z_i/L\}_{i=1,\ldots,2N}). \tag{32}
\]
The \(f^{(N)}\) function, depending on the Jacobi polynomials \(P_j^{(1,1)}\), can be expressed as a combination of \(f^{(1)}\) functions:
\[
f^{(N)}(\{z_i/L\}_{i=1,\ldots,2N}) = \sum_{1 \leq l \leq m \leq 2N} P^{(l,m)} f^{(1)} \left( \frac{z_l}{L}, \frac{z_m}{L} \right), \tag{33}
\]
where the coefficient \(P^{(l,m)}\) is defined as
\[
P^{(l,m)} = \begin{cases} +1 & \text{if } l \leq N < m \\ -1 & \text{if } l, m \leq N \text{ or } l, m > N \end{cases}. \tag{34}
\]
The $N$-th order correlation function is given by

$$g_T^{(N)}(\{r_i\}_{i=1,...,2N}) = \frac{\langle \hat{\psi}^\dagger(r_1) \ldots \hat{\psi}^\dagger(r_N) \hat{\psi}(r_{N+1}) \ldots \hat{\psi}(r_{2N}) \rangle_T}{\langle \langle \hat{\psi}^\dagger(r_1) \hat{\psi}(r_1) \rangle_T \ldots \langle \hat{\psi}^\dagger(r_{2N}) \hat{\psi}(r_{2N}) \rangle_T \rangle_T^{1/2}}$$  \hspace{1cm} (35)$$

and, from Eqs. (31) and (32),

$$g_T^{(N)}(\{z_i\}_{i=1,...,2N}) = \exp\{-\delta_L^2(T)f^{(N)}(\{z_i/L\}_{i=1,...,2N})/2\}.$$  \hspace{1cm} (36)$$

This general result shows that the spatial correlation function of phase fluctuating condensates is completely characterized by the parameter $\delta_L^2(T)$ and, therefore, by the phase coherence length $L_{\phi}$.

**IV. INTERFEROMETRIC MEASUREMENT OF THE SECOND ORDER CORRELATION FUNCTION**

The coherence of a matter wave can be studied by using interferometric methods. However, as standard interference experiments measure the first order correlation function of the field operator $\hat{\psi}$, they are very sensitive to phase noise introduced by the experimental apparatus. The method presented here is analogous to the original Hanbury-Brown and Twiss experiment \cite{23, 24} in which the spatially resolved second order correlation function $g^{(2)}(r_1, r_2, r_2, r_1)$ of a light source is obtained from intensity correlation measurements. As discussed before, for a highly elongated BEC $g_T^{(2)}(z_1, z_2, z_2, z_1) = 1$. This result suggests that a simple measurement of density correlations in the condensate is not sufficient to describe the coherence properties of the sample. Nevertheless, by measuring density correlations in the interference pattern generated by two spatially displaced copies of a parent BEC, it is possible to correlate the field operator $\hat{\psi}$ at four different positions and extract $g_T^{(2)}(z_1, z_2, z_3, z_4)$ directly. Compared to standard interference experiments, the main advantage of this technique is the intrinsic stability of the density correlation measurement against variations of the global phase between the interfering condensates.

In this section, we show how a matter wave Bragg interferometer can be used to characterize the second order correlation function of the condensate and measure its phase coherence length.
A. Interferometric scheme

Our interferometric sequence is shown in Fig. 2. The condensate is released from the magnetic trap and expands freely for 2 ms. This short time-of-flight is important to lower the density, thus reducing s-wave scattering processes occurring during the Bragg diffraction of the condensate [31]. The interrogation sequence consists of two $\pi/2$ Bragg pulses. Each pulse is composed of two counterpropagating laser beams of wave number $k$, detuned from the atomic transition. The first Bragg pulse splits the condensate in the two momentum eigenstates $|2\hbar k \rangle$ and $|0 \rangle$ along the axial direction ($z$). After a time $\Delta t$, a second $\pi/2$ pulse splits the condensates again, creating two interfering copies in each momentum state. The time interval $\Delta t$ between the two pulses sets the spatial overlap, $d = 2\hbar k\Delta t/m$, between the interfering BECs at the output ports of the interferometer. The relative phase of the two counterpropagating Bragg beams is externally controlled by an electro-optic modulator (EOM) and can be changed between the two pulses. This allows us to imprint an extra phase $\varphi$ which can be precisely tuned. Control of the EOM phase is crucial for our method, as described in Sec. IV-B.

Using the results derived in Sec. II, the atoms detected in the output port A (Fig. 2), after a total time-of-flight $t$, are described by the order parameter

$$\psi(r, d, t) = \frac{1}{2} \sqrt{\eta(r', t)} + \frac{1}{2} \sqrt{\eta(r, t)} \exp\{i[\delta\phi(z, z', t) + \alpha(z, z', t) + \beta(z, z') + \gamma(d)]\},$$

where $r' = r - d \hat{z}$ and $\eta(r, t)$ is the time-evolved density profile normalized to the total number of atoms in the parent condensate. The relative phase between the interfering condensates contains several contributions. $\delta\phi(z, z', t) = \phi(z, t) - \phi(z', t)$ describes the phase difference between $z$ and $z'$ that evolves from the phase fluctuations in the parent condensate. The term

$$\alpha(z, z', t) = \frac{m\lambda_z}{2\hbar \lambda_z} (z^2 - z'^2)$$

represents the non-uniform spatial phase profile developed during the mean-field-driven expansion. The mean-field gradient between the interfering BECs is responsible for a force repelling the centers of mass of the two clouds. This effect is described by the phase term

$$\beta(z, z') = \frac{m\delta v}{2\hbar} (z + z'),$$

proportional to the relative repulsion velocity $\delta v$ between the interfering condensates [32]. After the first Bragg pulse the relative phase of the atoms in the $|2\hbar k \rangle$ momentum state...

\[3 \hbar k \]
FIG. 2: a) Matter wave Bragg interferometer. The condensate is released from the magnetic trap and evolves freely for 2 ms. The sample is interrogated by the first $\pi/2$ Bragg pulse which splits the parent BEC in two copies with momenta 0 and $2\hbar k$. After a time $\Delta t$, the second $\pi/2$ Bragg pulse splits the condensates again and allows them to interfere. The time interval $\Delta t$ defines the displacement $d$ between the two interfering condensates. b) A typical line density profile at the output ports of the interferometer. The distance between the two autocorrelated copies ($d = 46 \mu m$) is comparable to the phase coherence length of the parent condensate ($L_\phi = 43 \mu m$). In the schematic of the matter wave Bragg interferometer, the distance $d$ has been exaggerated for clarity.
evolves with a characteristic frequency $\delta_{\text{Bragg}}$, given by the detuning of the lasers from the resonance of the two-photon transition \[33\]. Therefore, the last term,

$$\gamma(d) = \delta_{\text{Bragg}} \Delta t + \varphi = \delta_{\text{Bragg}} \frac{md}{2\hbar k} + \varphi,$$

(40)

represents a global phase depending on the detuning from the Bragg transition and the externally controlled phase $\varphi$.

The density of atoms at the output port A of the interferometer is given by

$$I(r, d, t) = \frac{1}{4} \eta(r, t) + \frac{1}{4} \eta(r', t) + \frac{1}{2} \sqrt{\eta(r, t) \eta(r', t)} \cos[\delta \phi(z, z', t) + \alpha(z, z', t) + \beta(z, z') + \gamma(d)].$$

(41)

The presence of strong phase fluctuations alters the interference pattern generated by the two autocorrelated condensates. In fact, when $d \approx L_\phi$ the phase term $\delta \phi$ can be comparable to $\pi$, modifying drastically and in an unpredictable way the position and the spacings of the interference fringes.

B. Method

Starting from Eq. (41), we want to calculate the density correlation function of the interference pattern, for an ensemble of identically prepared condensates at a given temperature $T$, averaged over all the global phase values $\varphi$. This averaging process is indicated by the symbol $\langle \ldots \rangle_{T, \varphi}$. It is therefore important that the phase delay $\varphi$ induced by the EOM is uniformly changed between 0 and $2\pi$. In Sec. II, we have shown that, for typical times-of-flight (tens of milliseconds), the evolution of the fluctuating phase of the condensate is basically frozen. This allows us to neglect the time-dependence of $\delta \phi(z, z', t)$. We also neglect the contribution of density modulations induced by the initial phase pattern on the Thomas-Fermi profile of the condensate. The validity of this approximation is verified below. Under these assumptions, we calculate the normalized density correlation function

$$
\gamma^{(2)}(r_1, r_2, d, t) = \frac{\langle (I_1 - \langle I_1 \rangle_{T, \varphi})(I_2 - \langle I_2 \rangle_{T, \varphi}) \rangle_{T, \varphi}}{\sqrt{\langle (I_1 - \langle I_1 \rangle_{T, \varphi})^2 \rangle_{T, \varphi} \langle (I_2 - \langle I_2 \rangle_{T, \varphi})^2 \rangle_{T, \varphi}}}.
$$

(42)

where $I_{1,2} = I(r_{1,2}, d, t)$. After a lengthy but straightforward calculation, the averaging process gives

$$\gamma^{(2)}(z_1, z_2, d, t) = \cos \left[ \frac{m}{\hbar} \left( \frac{\lambda_z}{d + \delta v} \right) (z_1 - z_2) \right].$$
\[ \gamma^{(2)}(z_1, z_2, d, t) \] results from the product of two different terms: the first is a periodic function, whose argument is the contribution of the mean-field energy to the phase profile (ballistic expansion and relative repulsion between the interfering condensates); the second is an exponential term which corresponds to the \( g_T^{(2)} \) function of the parent phase fluctuating condensate. The decay constant of this function is given by the phase coherence length of the condensate (see Eq. 20).

From the experimental point of view, the averaging process described above is equivalent to the following procedure: The radially integrated density profile \( I = I(z, d, t) \) at the output port A of the interferometer is measured for different values of the global phase, uniformly distributed in the range \( 0 \leq \varphi < 2\pi \); then the average value \( \langle I \rangle_{T,\varphi} \) is calculated and used to determine \( I - \langle I \rangle_{T,\varphi} \) for each experimental realization. These profiles, averaged according to Eq. (42), give a measurement of \( \gamma^{(2)}(z_1, z_2, d, t) \). We evaluate the density correlations as a function of the separation \( s = z_2 - z_1 \). For simplicity, we choose symmetric positions around the center \( (z = d/2) \) of the interference pattern in the output port A. The positions in Eq. (26) are defined such that \( z_1 = \bar{z}_1 \) and \( z_2 = \bar{z}_4 \) (see Fig. 2). The method described here allows us to characterize the dependence of the correlation function

\[
\gamma^{(2)}(s, d, t) = \cos \left[ \frac{m}{\hbar} \left( \frac{\dot{\lambda}_z}{\lambda_z} d + \delta v \right) s \right]
\times \exp \left[ -\delta^2_L(T) f^{(2)}(\bar{z}_1/L, \bar{z}_2/L, \bar{z}_3/L, \bar{z}_4/L)/2 \right]
\]

on the separation \( s \) for any fixed displacement \( d \) between the interfering condensates.

C. Experimental results and numerical simulations

We perform the experiment with \(^{87}\text{Rb} \) condensates in the \( F = 1, m_F = -1 \) state. The atoms are confined in a highly elongated magnetic trap with cylindrical symmetry, the long axis lying in the horizontal plane. The confining potential has an axial frequency \( \omega_z = 2\pi \times 3.4 \) Hz and a radial frequency \( \omega_\rho \) which is varied between \( 2\pi \times 300 \) Hz and \( 2\pi \times 380 \) Hz. Further details on the experimental apparatus can be found in [18]. After the BEC formation, we let the system thermalize in the magnetic trap for typically 4 s in presence of radio frequency shielding [34]. That time is important to reach an equilibrium condition in which
any quadrupole oscillation has been damped down. As shown in Fig. 2, our matter wave interferometer consists of two $\pi/2$ Bragg diffraction pulses. Each of them is composed of two counterpropagating laser beams, detuned by about 3 GHz from the atomic transition. This detuning suppresses spontaneous scattering of photons during the interrogation time. The Bragg pulse duration of 100 $\mu$s is sufficiently short not to resolve the momentum distribution of the atoms in the condensate and long enough to avoid higher order Bragg diffraction processes. A fixed frequency difference is set between the two counterpropagating beams to match the Bragg condition. The condensate is released from the magnetic trap and after 2 ms of time-of-flight is probed by the two-pulse sequence of the interferometer. The atomic cloud is detected after the ballistic expansion by resonant absorption imaging.

Figure 2b shows a typical line density profile of an interference pattern where the distance between the two autocorrelated copies ($d = 46 \mu$m) is comparable to the phase coherence length of the parent condensate ($L_\phi = 43 \mu$m). Because of the stochastic nature of phase fluctuations, the fringe spacing is not regular and differs in each experimental realization. This experimentally demonstrates that the fluctuating phase of the condensate can significantly change on distances comparable with the phase coherence length of the sample. Even if each single image shows high contrast, the interference pattern is completely washed out when we average a significant number of realizations.

The results of standard interference experiments are related to the correlations of the wavefunction and therefore are very sensitive to phase instabilities. Figure 3 shows the interference signal obtained by measuring the number of atoms in an interval of width $0.2 \times L$ around the center of the interference pattern ($z = d/2$) at the output port A, as a function of the global phase $\varphi$ controlled by the EOM. This signal is normalized to the corresponding number of atoms in the parent condensate. The two plots correspond to different displacements $d$ between the interfering condensates. A small displacement is related to a short time interval between the two interrogation Bragg pulses. In that case, the contribution of phase fluctuations and the effect of technical phase noise introduced by the experimental apparatus are both negligible. Therefore, according to Eq. (41), when $d \ll L_\phi$ and $\Delta t$ is small compared to the characteristic time stability of our Bragg pulses, the normalized signal oscillates sinusoidally with high contrast. For $d$ approaching $L_\phi$, the random phase introduced by the phase fluctuations washes out the oscillation. If external disturbances can be neglected, the contrast of the oscillations is directly related to the
FIG. 3: The number of atoms measured in the interval $d/2 - 0.1 \times L < z < d/2 + 0.1 \times L$, around the center of the interference pattern detected at the output port A, is plotted as a function of the phase $\varphi$ controlled by the electro-optic modulator. The signal is normalized to the corresponding number of atoms in the parent condensate. The two sets of data correspond to different displacements $d$ between the overlapping condensates. The solid line is obtained by fitting the experimental data with a sinusoidal function. The measurements refer to condensates with about $3 \times 10^5$ atoms, a typical axial size of $L = 180 \mu m$ and a temperature $T = 170 \, nK$.

first order correlation function $g^{(1)}$ at a given displacement $d$. However, as $d$ increases, the external disturbances also increase and produce a random phase noise which destroys the oscillating behavior and hides the effect of phase fluctuations on the detected signal.

This problem can be solved by using the method described in Sec. IV-B. The measurement of intensity correlations, in combination with the subsequent averaging process, has the major advantage of being insensitive to technical phase noise introduced by the experimental apparatus. Figure 4 shows the correlation function $\gamma^{(2)}(s, d, t)$ extracted from a set of 29 line density profiles corresponding to $5.0 \times 10^5$ condensed atoms at a temperature $T = 216 \, nK,$
FIG. 4: Circles: Correlation function $\gamma^2(s, d, t)$ extracted from a set of 29 line density profiles. The data correspond to samples with $5.0 \times 10^5$ condensed atoms at a temperature $T = 216$ nK, detected after a total time-of-flight $t = 37$ ms. The displacement between the interfering BECs is $d = 35 \mu m$. The bars on the experimental points represent the statistical errors. Crosses: Numerical simulation which takes into account the time dependence of the fluctuating phase and of density modulations, modelled on the experimental parameters. Solid line: Fit to the experimental data using the model function of Eq. (45). Dashed line: Second order correlation function $g^{(2)}_T(s, d) = g^{(2)}_T(z_1/L, z_2/L, z_3/L, z_4/L)$ extracted from the fit to the experimental data. The phase coherence length of the sample is graphically indicated on the plot.

detected after a total time-of-flight $t = 37$ ms. The displacement between the interfering BECs is $d = 35 \mu m$. The experimental data is compared with a numerical simulation which produces random phase patterns according to the experimental conditions and uses Eq. (37) to describe the evolution of the order parameter. The numerically calculated points shown in Fig. 4 are obtained by following the same averaging procedure we have applied to the experimental data. This kind of analysis includes the time dependence of the fluctuating phase and of the density modulations induced by the initial phase pattern. The solid line is the result of a fit to the experimental data. According to Eqs. (37) and (38), the model function

$$\cos(a \cdot s) \exp[-b \cdot f^{(2)}(z_1/L, z_2/L, z_3/L, z_4/L)/2]$$  \hspace{1cm} (45)$$

contains only two free parameters. The curves clearly show the damped oscillating behav-
FIG. 5: Direct comparison between the measured phase coherence lengths and the theoretical values, calculated according to Eq. (20) by using the measured numbers of atoms, temperatures and trapping frequencies. The dotted line with slope 1 is used to compare experiment and theory. The bars on the plotted points indicate statistical errors. The relative systematic uncertainties on the calculated and measured phase coherence length are 26% and 15%, respectively. This figure has previously been shown in [22].
quantitative agreement between experiments and theory.

V. CONCLUSION

In this paper, we have studied the coherence properties of phase fluctuating Bose-Einstein condensates. In highly elongated BECs the thermal excitation of quasiparticle modes can significantly reduce the coherence length of the system. Starting from the results of Petrov et al., we have derived a general formula for the \( N \)-particle correlation function. The second order correlation function has been studied in detail and its limits both around the center of the condensate and in the local density approximation have been analyzed. In particular, we have discussed a method to directly characterize the second order correlation properties of the system. An analytic theory that describes the free evolution of the condensate phase has been developed to closely model the measurement process. Using a Bragg diffraction interferometer, we have measured the density correlations of the interference pattern generated by two spatially displaced copies of a parent BEC. This kind of measurement allows to correlate the field operator \( \hat{\psi} \) of the parent condensate in four different \( z \) positions. The averaging process directly gives the second order correlation function. The experiment confirms our theoretical predictions and demonstrates a method to measure the phase coherence length of the condensate. Compared to usual interference experiments this technique has the advantage of being insensitive to the global phase noise introduced by the experimental apparatus. The method presented here is in direct analogy to the original Hanbury-Brown and Twiss experiment and demonstrates the possibility of using density correlation measurements to study the coherence properties of Bose-Einstein condensates.

[34] We measure the typical thermalization times of our condensates by performing experiments of BEC growth. After times of few hundreds of milliseconds the system reaches an equilibrium condition.
[35] For example, a change in the release velocity of $5.5 \times 10^{-3} v_{rec}$, where $v_{rec} = \hbar k/m = 5.9 \mu\text{m/ ms}$ is the recoil velocity on the $D_2$ line, leads to a phase change of $\pi/2$ during a time $\Delta t = 3 \text{ ms}$ between the Bragg pulses. This value approximately corresponds to the stability of the release velocity in our experimental apparatus.
