ABSTRACT

We present a new method for determining the column density of erupting filament material using state-of-the-art multi-wavelength imaging data. Much of the prior work on filament/prominence structure can be divided between studies that use a polychromatic approach with targeted campaign observations and those that use synoptic observations, frequently in only one or two wavelengths. The superior time resolution, sensitivity, and near-synchronicity of data from the Solar Dynamics Observatory’s Advanced Imaging Assembly allow us to combine these two techniques using photoionization continuum opacity to determine the spatial distribution of hydrogen in filament material. We apply the combined techniques to SDO/AIA observations of a filament that erupted during the spectacular coronal mass ejection on 2011 June 7. The resulting “polychromatic opacity imaging” method offers a powerful way to track partially ionized gas as it erupts through the solar atmosphere on a regular basis, without the need for coordinated observations, thereby readily offering regular, realistic mass-distribution estimates for models of these erupting structures.

Key words: methods: data analysis – radiative transfer – Sun: activity – Sun: coronal mass ejections (CMEs) – Sun: filaments, prominences – Sun: UV radiation

Online-only material: animations, color figures

1. INTRODUCTION

The mass and structure of prominences/filaments are of interest in several aspects of the study of the corona. Since the launch of Hinode and its Solar Optical Telescope (SOT; Kosugi et al. 2007; Tsuneta et al. 2008), observations of the dynamic structures in prominences with SOT data (Berger et al. 2011) have underlined the difficulties of explaining prominence dynamics. Development of radiative transfer models (e.g., Labrosse & Gouttebroze 2004; Anzer & Heinzel 2005) requires an understanding of the fine-scale mass structure and radiation field, while oscillations in prominences can be used for diagnosis of the magnetic field strength only if their mass can be accurately estimated (Oliver 2009, and references therein). Models that seek to replicate the initial conditions of filament eruptions (Low et al. 2003), and those that address the ensuing propagation into the heliosphere (DeForest et al. 2012) must take into account the effects of gravity (Spicer et al. 2006) and composition (Kilper et al. 2009) on these concentrations of material that are at least an order of magnitude denser than the surrounding corona (e.g., Bommier et al. 1994; Jejič & Heinzel 2009).

The most established methods of measuring mass distributions use Thomson scattering of photospheric light by free coronal electrons (Hundhausen et al. 1994) to estimate the total amount of mass in prominences and (interplanetary) coronal mass ejections (CMEs; Vourlidas & Howard 2006, and references therein). More recently, investigators have used the amount of material evacuated in the dimming of the EUV corona to estimate the amount of mass lost to a CME/ICME (Harrison & Lyons 2000; Aschwanden et al. 2009), showing consistency with parallel observations from Thomson scattering estimates.

At wavelengths shorter than the Lyman series limit (912 Å), cool plasma is optically thick due to photoionization, principally of neutral hydrogen and neutral or singly ionized helium. The product of abundance and cross-section for photoionization of other species is negligible compared with these three. This continuum absorption is used in studies of the interstellar medium (see Vennes et al. 1993; Fruscione et al. 1994, and references therein) to calculate the column density ($N_{i,J}$) of these species along the line of sight, where $i$ is the element, and $J$ is the ionization stage ($J \in \{I, II, \ldots, Z\}$), since the total opacity at a given wavelength, $\tau(\lambda)$, is given by

$$\tau(\lambda) = \sum_i \sum_J N_{i,J} \sigma_{i,J}(\lambda),$$

where $\sigma_{i,J}$ is the cross-section for absorption due to photoionization for species $i,J$. This allows the column mass $M$ along the line of sight to be estimated as

$$M = \sum_i m_i \sum_J N_{i,J}.$$

The effect was also noted in the solar transition region by Schmahl & Orrall (1979) as evidence of H I and He i—and therefore partial ionization—in the chromosphere and transition region. (See also the work of Orrall & Schmahl 1976; Kanno 1979; Kanno & Suematsu 1982.)

The most frequent investigations of column-density structure on the Sun are those that estimate how much light is attenuated by a filament—i.e., its opacity—and, hence, total mass along the line of sight in each spatial resolution element (Equation (2)). Since both band-pass imager and slit-spectrometer data of the Sun exist in the EUV, these investigations have consisted of various combinations of images at a single wavelength or wavelength band (Gilbert et al. 2006), images at multiple wavelengths (Golub et al. 1999; Engvold et al. 2001), spectral line measurements in the EUV and (often) H α data (e.g., Schmieder et al. 1999; Mein et al. 2001).

Gilbert et al. (2005, 2006) have developed and applied a technique for estimating the mass of limb-crossing
prominences using EUV images at 195 Å only. This so-called spatial-interpolative approach estimates the background emission and prominence opacity. An interesting point is that they make use of the fact that erupting prominences eventually reveal something close to the original background emission, albeit at a later point in time. This allows a “temporal-interpolative” approach, to which we return later. Though not strictly “monochromatic,” we use the term in this article to refer to all single-wavelength/passband methods.

A logical extension of the above method is to use the information from several EUV wavelengths, over a sufficiently broad range, so that the cross-section for photo-absorption varies while other variables are assumed to hold constant. If all the associated radiation escapes from the corona, where the pressure scale heights are large, then this approximation can be made. Such “polychromatic” approaches include: those which are (coronal) image-based (Golub et al. 1999; Gilbert et al. 2011); those that use coronal line spectroscopy (Kucera et al. 1998; Anzer & Heinzel 2005); and those that include emission from the transition region and/or chromosphere (e.g., Schmieder et al. 1999; Mein et al. 2001), often interpreted with the aid of non-LTE radiative transfer modeling to gain further insight into the detailed ionization and mass structure of a filament. Motivated to constrain filament models, for example, Anzer & Heinzel (2003) and Schwartz et al. (2004) used a radiative model (Heinzel et al. 2003) to infer the height of filament material above the solar surface, and to differentiate between morphological filament models. The third of the listed techniques is still developing. Labrosse et al. (2011) most recently applied it to Hinode EUV Imaging Spectrometer spectra (EIS; Culhane et al. 2007), while Gilbert et al. (2011) exploited Solar and Heliospheric Observatory (SOHO) imaging and spectroscopic data (Domingo et al. 1995). We refer the reader to the recent review by Labrosse et al. (2010) for an excellent treatment of these and other prominence diagnostics.

A distinct disadvantage of the spectroscopic approaches, pragmatically speaking, is that contemporary EUV spectrometers have a limited field of view, so that the observations must be targeted. Hα measurements, on the other hand, are typically ground based and so are susceptible to weather-imposed limitations. As a result, these methods have not been used on a regular basis.

A persistent unknown in much of this work is the background radiation field, here denoted by $I_b$, that is attenuated by the filament material. The background corona is clearly variable on short and long spatial and temporal scales, but a view of it is blocked by the material under investigation. This has been treated by interpolating between points in the background on either side of cool masses (Kucera et al. 1998), with additional consideration of the profile of background coronal emission off-limb (Gilbert et al. 2011; Golub et al. 1999). However, because of the highly structured nature of the solar atmosphere, a better background model can be obtained by observing coronal emission in the absence of the absorbing structure, such as before and/or after a filament eruption. Gilbert et al. (2005) used both a “temporal-interpolative” approach and a “spatial-interpolative” approach to measure the column depth of a prominence that erupted from the southeast solar limb; their method was later applied to a larger sample of erupting and non-erupting prominences (Gilbert et al. 2006). Similarly, Kucera & Landi (2008) use a temporal-interpolative approach in analysis of data from an erupting prominence structure taken with the SOHO/SUMER spectrometer (Wilhelm et al. 1995).

It is worth pointing out that photometric measurements are complicated by the presence of filament cavities (Gibson et al. 2010) where, for coronal lines, there is lower emissivity in both the cavity and the filament itself. This effect is referred to as “volume blocking” or “emissivity blocking” (Heinzel et al. 2003). The amount of attenuated radiation emerging from behind the filament is difficult to disentangle from radiation emitted in the foreground, but a promising alternative to the interpolative approaches is to use the X-ray transparency of filament material (Anzer et al. 2007) and assume that the EUV background emission can be scaled to match the spatial soft X-ray distribution (Heinzel et al. 2008). While this, too, is an assumption, it does address the issue of reduced emission in the cavity.

Since the launch of NASA’s Solar Dynamics Observatory (Pesnell et al. 2012) incorporating the Advanced Imaging Assembly (AIA; Lemen et al. 2012), we have access to much higher-cadence observations of the solar corona, with data simultaneous or near-simultaneous in several EUV wavelengths. This allows us to apply a temporal-interpolative approach to measure the total background and foreground emission around cool-material structures in apparent motion across the Sun, often at several points close in time to the transient absorption taking place.

In this article, we describe the application of two methods—one monochromatic, the other polychromatic—to AIA observations of cool material returning from a spectacular filament eruption. Although the eruption on 2011 June 7 is successful, producing a CME, some filament material returns to the solar atmosphere and surface, and our aim is to infer the density of material from its obscuration of the background corona. We describe two approaches to achieving this aim. The first approach calculates the opacity of the material from data taken in a single AIA filter, an approach also used in L. van Driel-Gesztelyi et al. (2013, in preparation) but described here in detail. The second approach uses arguments first made by Kucera et al. (1998) to separate the column density from the product of filling factor and geometrical depth using observations made at multiple wavelengths. In both cases, we use properties of the opacity due to H i, He i, and He ii photoionization continua to give a more powerful lower-limit estimate of the total hydrogen column density along the line of sight, using the vastly improved cadence and sensitivity of AIA data. Lastly, we compare the results of these approaches.

2. OBSERVATIONS

The observations used in this work were recorded by AIA on 2011 June 7, in the period 06:30–08:00 UT. The region of interest is around NOAA active region 11226, which produced an M2.7-class X-ray flare and a spectacular filament eruption, in which most of the filament mass appears to have returned to the Sun. The returning filament mass is the subject of this study, where we estimate the column and volumetric densities. We focus on two primary targets in which to diagnose the total hydrogen column density, $N_H$.

Target 1 is a large concentration of returning material that appears to fall unhindered by the solar magnetic field, suggesting high plasma $\beta$, consistent with a low ionization degree. The material is shown in Figure 1(b).

Target 2 is an area to the east of the active region, where returning filament mass arrives at what resembles a Y-shaped coronal magnetic null point (Figure 6; L. van Driel-Gesztelyi et al. 2013, in preparation). Material that appears dark in the
analyzed here. Because the above approximation is expressed in terms of the helium cross-sections, it allows us to more accurately gauge the total hydrogen column density for weak degrees of \( \text{He}\,\,\,\text{ii} \) ionization, independent of the ionization degree of hydrogen, which fully ionizes at temperatures much lower than does helium. Accordingly, and considering the inequality sign in Equation (4), our estimate of \( N_{\text{He}} \) will be a lower limit; the lower the ionization degree of helium, the more this value is likely to represent an accurate value rather than just a lower limit.

### 3.1. Polychromatic Measurements

Kucera et al. (1998) write the following expressions for the observed EUV intensity at a given point on a filament, considering the effects of a pixel filling factor along the line of sight, \( f \):

\[
I_{\text{obs}} = I_0 \left[ f e^{-\tau} + (1 - f) \right] + I_f
\]

\[
= I_0 - f I_0 (1 - e^{-\tau}),
\]

(5)

where

\[
I_0 = I_b + I_f.
\]

(6)

This allows Equation (5) to be rewritten as

\[
1 - \frac{I_{\text{obs}}}{I_0} = f \frac{I_0}{I_0}(1 - e^{-\tau})
\]

\[
= G(1 - e^{-\tau}),
\]

(7)

(8)

where the factor \( G \) combines the two unknown geometrical factors of the fraction of emission behind the absorbing material, \( I_b/I_0 \) and the filling factor that describes how much of the pixel area is filled by this material. Anzer \\& Heinzel (2005) note that the former term can potentially be appreciably less than unity, particularly when the absorbing material is low in the atmosphere. The quantity on the left-hand side of Equation (7) is an observable quantity, denoted as the absorption depth, \( d \),

\[
d \equiv 1 - \frac{I_{\text{obs}}}{I_0}
\]

(9)

\[
d(\lambda) = G[1 - e^{-\tau(N_{\text{He}};\lambda)}]
\]

(10)

i.e.,

\[
F(G, N_{\text{He}}; \lambda) = d(\lambda).
\]

(11)

In this case, \( d(\lambda) \) can be fitted to a function \( F \) if there are independent observations at a sufficient number of wavelengths.

The above method is appropriate where we have simultaneous observations of the same target. This also holds true for near-simultaneous observations, provided that the target does not change shape or density appreciably between measurements. Thanks to the cadence of AIA, this is true in the case of Target 1. We therefore cross-correlate images of monochromatic intensity at a sufficient number of wavelengths. Since this property ought to scale largely with \( \tau(\lambda) \) between measurements at different wavelengths.

In this analysis, we use a Levenberg–Marquardt least-squares minimization algorithm to find the best fit to the measured \( d(\lambda) \) in Equation (10). An example fit is shown in Figure 3. Since there are two free parameters of \( F \), we require observations in at least three wavelengths to constrain them. We use data from the 94, 131, 171, 193, and 211 Å channels. Although the images are near-synchronous rather than being truly cotemporal, the cadence of the observations is such that the form of Target 1 does...
Figure 2. (a) Cross-sections for photoionization, $A_i \sigma_i J$, for the three principal contributors in the short EUV and (b) ratio of $A_i \sigma_i J$ to $A_H \sigma_H$. The gray shaded box indicates (horizontally) the range of EUV wavelengths shorter than the He II ionization edge that are observed by AIA, as well as the range within which the abundance-weighted cross-section can deviate by a factor of $\leq 2$ from that of H I (vertically).

Figure 3. Example of the result of fitting observed $d(\lambda)$ at all AIA wavelengths below 227 Å. Data points are taken from a measurement inside the large mass shown in Figure 1(b). Large circles with error bars: $d(\lambda)$. Small circles joined by solid line: values of $d$ due to the best fit to Equation (10), where the hatched envelope represents the bounds of the best fit $\pm 1\sigma$. (A color version of this figure is available in the online journal.)

3.2. Opacity Measurements at a Single Wavelength

The filament mass concentrations in Target 2 move, and deform, much more rapidly than Target 1, so that it is not possible to convincingly co-register images taken at different times and wavelengths. This being the case, we cannot use near-simultaneous measurements of intensity reduction at different wavelengths to fit Equation (10). However, since we can no longer estimate $G$ independently of $N_H$, we can simply set...
$G = 1$ and accept that we will make an underestimate of the column density in this way, since this implies a unity filling factor, and that all EUV emission $I_0$ is behind the erupting filament material. In this case, we would rewrite Equation (10) for a single wavelength as simply

$$\tau(\lambda) \geq \ln I_{0,\lambda} - \ln I_{\text{obs},\lambda}. \quad (12)$$

Using this monochromatic opacity, we are again able to calculate a map of the lower limit to this quantity and of the resulting column density shown in Figures 4 and 6(c). Note that this type of opacity map is used to co-register the near-simultaneous images at different wavelengths in Section 3.1.

The area covered by the field of view in Figure 6 is, fortunately, unobscured by returning filament material until around 06:50 UT. There is a pronounced dimming around this region following the transit of a coronal wave, but the period between 06:44 and 06:48 UT lies between the passage of the wave and the arrival of falling filament material. Therefore, we model the background emission, $I_0$, as the mean intensity of images taken during this interval (Figure 6(a)). Because we calculate $I_0$, in this case, from a time average of these data, we estimate the measurement error on the background at each pixel as the quadrature sum of the photon noise from each image and the standard deviation of intensity in that pixel in time.

4. ANALYSIS

4.1. Polychromatic Method

We define the edge of Target 1 as the level where $G = 0.6$ (Figure 4). This level is set arbitrarily, but seems to match the visual edge of the target well in the portion of the FOV that was unobscured in $I_0$. The restriction of our analysis to the area indicated in Figure 4 reflects the fact that some portions of the image used as $I_0$ were already obscured by absorbing material. The animation that accompanies Figure 1 in the online edition of the journal shows that other, fainter filament material moves between the times indicated between Figures 4(a) (constituting $I_0$) and 4(b) ($I_{\text{obs}}$), revealing an elongated bright structure behind Target 1. This would tend to cause an underestimate of $N_H$ in the affected pixels, since the bright structure was not accounted for in $I_0$, so that the drop in intensity would in fact be slightly larger.

The detailed map of best-fit column density (Figure 4(a)) shows a concentration of material toward the lowest part of the target, with column densities of $N_H \sim 10^{20}$ cm$^{-2}$. We note that these values are rather larger than those previously reported in either erupting or quiescent filaments (Penn 2000; Gilbert et al. 2005; Labrosse et al. 2010). The numeric values and their associated 1σ errors along two slices are shown in Figure 5. While the variance along a slice in $N_H$ is noticeable, the corresponding profiles of $G$ are much less variable. In fact, the value of $G$ seems remarkably stable across the target: Given that Target 1 is likely to have reasonably uniform $I_0/I_0$ on larger scales, its small-scale uniformity indicates that the pixel filling factor, $f$, may be rather smooth. $G$ also lies close to unity, which indicates that $f$, too, must be rather high. The absolute value of $I_0/I_0$ is tricky to determine (without using stereoscopic data), but the high value of $G$ indicates that the mass must be several emission scale heights into the corona.

We should point out that the values along the slices include all the values fitted in the FOV shown in Figure 4, not only those within the target shown, which leads to the more wildly varying fitted values—from outside the $G = 0.6$ contour—being plotted at the edges of Figure 5(a).

In order to estimate mean volumetric (number) densities in this structure, we divide $N_H$ by a characteristic path length through the material. We choose the FWHM of $G$ (14′′) as our indicator, equivalent to a path length of $l = 10^9$ cm. The estimates of $n_H$ are therefore dependent on the value of $l$ being constant; although this is almost certainly an oversimplification for any given point in the target, it serves as a guide for estimating the total hydrogen density, which reaches $n_H \gtrsim 10^{10}$ cm$^{-3}$.

4.2. Monochromatic Method

As stated in Section 3.2, the primary object to which we apply our monochromatic method is Target 2 (Figure 6(b)). In this
Figure 5. (a) Total hydrogen column density, and inferred volumetric density, along the slices through Target 1 shown in Figure 1(b). (b) Along the same slices, the value of the geometric factor, $G$, is plotted. For both figures, the dashed line corresponds to the dashed slice in Figure 1(b), while the solid line corresponds to the solid slice.

(A color version of this figure is available in the online journal.)

case, we have used data from the AIA 193 Å channel because of its superior signal-to-noise ratio. In contrast to our approach in Section 4.1, we do not isolate any one piece of material in the reduced field of view shown. However, we once again take profiles of $N_{\text{H}}$ through a concentration of absorbing material, seen to be moving eastward (negative x-direction) from the apparent Y-point. The positions of these profiles are indicated in Figure 6(c), and the corresponding values along each are shown in Figure 7. It is noticeable that $N_{\text{H}}$ varies more smoothly across this target than in Target 1 (Figure 5). Although the nature of the monochromatic analysis is a mapping from a more smoothly varying intensity to $\tau$ (rather than a fit of two free parameters to multiple data points), the background being time-averaged (Section 3.2) may also contribute to this smoothness.

More generally, the amount of material contained in these thinner “threads” is still substantial, with lower limit values in the range $N_{\text{H}} \gtrsim 10^{18} - 10^{19}$ cm$^{-2}$, similar to those seen in more extended prominences (Kucera et al. 1998). In order to estimate the volumetric density $n_{\text{H}}$, we again assume a representative path length equivalent to the FWHM of the structure in the plane of sky, which we estimate from Figure 7 as $4^\prime$ ($3 \times 10^8$ cm). Again, this is an oversimplification, but it suggests values of $n_{\text{H}} \gtrsim 10^{10}$ cm$^{-3}$ within this target filament mass, comparable with those found for the much larger Target 1.

4.3. Comparison of Methods

Since the monochromatic method is more appropriate to fast-changing/-moving features, where we cannot co-register images taken at different times, it is of interest to gauge how well this method performs when compared with our polychromatic approach (Section 3.1) for Target 1.

Figure 8 shows correlation plots of monochromatic $N_{\text{H}}(\lambda)$ to polychromatic $N_{\text{H,fit}}$. In the two shortest-wavelength channels, the signal to noise is rather poor, and the scatter in correlation is large. However, for the 171, 193, and 211 Å channels, the
scatter is less, and \(N_{\text{H}}(\lambda)\) is shown to be consistently underestimated when compared with \(N_{\text{H, fitted}}\). In the same figure, we have color coded the points to show the fitted value of \(G\); in general, the smaller the value of \(G\) is, the greater the underestimate of the column density will be when only a single wavelength is used. This is perhaps unsurprising, since we set the filling factor arbitrarily to unity in calculating the monochromatic values.

5. DISCUSSION

Each of our approaches to determining \(N_{\text{H}}\) depends upon determining its value through the expression in Equation (4). We assume a fixed relative abundance for helium (Section 3), but it should be noted that Gilbert et al. (2007) and Kilper et al. (2009) find variation of the He/H abundance ratio in prominences, pointing to cross-field diffusion of neutral H and He as the most likely cause of stratification of this ratio. However, their finding is unlikely to apply since the dynamic timescale in the targets analyzed here is much shorter than the diffusion timescale (Gilbert et al. 2007). In eruptive events, Kilper et al. (2009) also find that the ratio tends to homogenize in the hours leading up to eruption, and we suggest that the mixing of plasma induced by the eruption is likely to contribute further to this homogenization. Work by Bemporad et al. (2009) uses the Hinode EUV Imaging Spectrometer (Kosugi et al. 2007; Culhane et al. 2007) to show significant, spatially unresolved velocities (\(\xi \lesssim 100\ \text{km s}^{-1}\)) at the location of an erupting prominence, which may support the picture of mixing.

Since the absorbers of EUV radiation we consider here are ions and neutrals in a partially ionized plasma, we can only measure the total column density of neutral and partially ionized helium (thus, hydrogen), and estimate \(n_{\text{H}}\); we can make no comment on the density of free electrons in this plasma beyond the trivial \(0 < n_{e} < (n_{\text{H}}/0.83)\), since the ratio \(n_{e}/n_{\text{H}}\) will depend upon the detailed parameters of the plasma and radiation field. Any fixing of the electron-to-hydrogen ratio to the usual coronal value of 0.83 is likely to lead to overestimation of \(n_{e}\) in the targets considered here.

Similarly, we are unable to make estimates of the ionization degree of helium, since: (1) as we have shown, the cross-section for absorption of He i is very close to that of He ii (Section 3); and (2) we have no useful data longward of the He ii ionization edge.
(227 Å; Section 3.1). Nor do we have data in both the helium continua and the H I Lyman continuum (504 Å < λ < 912 Å), which precludes measurements of He/H abundance variations.

We also do not consider the information in the distribution of N_H about how thick Target 1 might be at each pixel—the concentration of mass in the lower parts is ignored, along with information that it may impart. The method can of course be inverted, assuming a constant value for n_H to infer a spatially varying path length through the material.

The approaches used in this article lack an advantage of the spectroscopic approaches favored by previous authors. For example, we do not analyze emission from individual emission lines, some with very short scale height, to make estimates of the effect of lowered emission due to the cavity around a filament as Heinz et al. (2003) do. However, in the case of an erupting filament, the cavity rapidly expands, so that both I_0 and I_r are sampled within the cavity at the time of our measurements. Our use of emission from filters rather than at individual wavelengths is not a difficulty, however, since the cross-sections for photoionization depend only on wavelength.

An earlier, spectroscopic analog of the work by Kucera et al. (1998) applied to erupting prominences can be found in Penn (2000), who uses five emission lines between 555 and 630 Å to derive column densities of around 5 × 10^{12} cm^{-2}. Although there are already likely to be significant differences between the amount of material studied by Penn and that studied here, they also use lines in a region of the spectrum that has been shown by Mein et al. (2001) and Gilbert et al. (2011) to suffer from saturation of the photo-absorption effect. The much higher column densities we find may be due to the lack of these saturation effects at the shorter wavelengths studied here.

5.1. Underestimation Factors

In Figures 5 and 6, we infer the volumetric electron density n_e on the right-hand axis of the plotted profiles. In each case, we infer the density by estimating a path depth equivalent to the width of the feature observed. For the profiles in Target 1, we estimate a path length of 14′′ (∼10^6 cm); for the narrower feature in Target 2, we estimate a path length of 4′′ (∼3 × 10^6 cm). These depths are estimated from the FWHM of the corresponding N_H profiles.

Studying the He I D_1 and H_z lines in a number of prominences, Bommer et al. (1994) find mean volumetric electron densities of (2.1 ± 0.7) × 10^{10} cm^{-3}. The values we infer from a monochromatic measurement of our targets are consistent with this mean, if a little on the low side. However, the monochromatic estimates are systematically lower than those derived from the multi-wavelength fit to d(λ) by as much as an order of magnitude. In addition to this effect, there is the consideration that our estimates are again underrepresentations of the true column depth if a non-vanishing fraction of the helium along the line of sight is fully ionized, a distinct possibility if heating takes place in or around this material. In an erupting structure, Kucera & Landi (2008) find evidence of emission at log T_e ∼ 5.0.

As already indicated above, the column depth can become so large that it effectively blocks all emission from behind. Gilbert et al. (2011) recently encountered problems with the λ625 line, finding that the estimate of N_H at λ195 was much larger. The saturation of the effect at longer λ will cause the depth to be underestimated: At some limiting value of τ, no additional photons can be scattered/absorbed by the absorbing mass. Further evidence of this effect is shown by Heinz et al. (2008) as disagreement between estimates of the continuum opacity derived at Mg λ625 with that inferred from τ_H. The former shows an underestimate of column density compared with estimates from the latter Gilbert et al. (2011). Each paper attributes the problem of underestimated mass (as do Kucera et al. 1998) to the saturation effect described above.

These effects would suggest that the ratio between N_H and the column depth of all absorbers deviates from the lower limit of Equation (4). However, there is an additional term that may lead to our underestimation of N_H. As stated in Section 3, we do not consider the effects of emission from the prominence material in the EUV passbands analyzed. There could, in fact, be emission in lines over a wide range of temperatures; O’Dwyer et al. (2010) have recently performed a detailed analysis of the emission lines (and corresponding temperatures) to which AIA is sensitive. Differential emission measures constructed from sections of a prominence by Parenti & Vial (2007) suggest that there is a considerable amount (though not a majority) of material at log T_e > 4.8. Either of these cases would suggest that the effect on our results will be to make them a lower limit to the local filament mass, as already expected. Furthermore, in response to the work of Kucera et al. (1998), Engvold et al. (2001) point out that the former’s results are susceptible to emission from hot lines in and around filaments before eruption. They are unable to establish the contribution of these hot lines to the total observed emission, but filaments are certainly susceptible to heating before and during eruption, as shown by Kucera & Landi (2008), often with apparently coronal-temperature emission (e.g., Liewer et al. 2009; Sterling et al. 2011), as is perhaps seen in Target 2 (Figure 6). It is less clear whether there is heating of Target 1, the target in which we apply Kucera et al.’s (1998) method, as it returns to the lower solar atmosphere, but this possibility is certainly worth bearing in mind. In any case, the measurements made here would still serve as a lower limit.

5.2. Advantages to This Method

Despite the disadvantages mentioned above, our approaches have a number of advantages.

1. They require no coordinated observing campaigns, only coteemporal or near-co-temporal images of an erupting (or otherwise rapidly moving) filament in several EUV wave-lengths. Full-Sun EUV observations are carried out in a patrol like fashion all the time by AIA, so that the approaches can be applied whenever data are available.

2. Because we use lines in the range where the helium cross-sections are at least as important as that of hydrogen, the method is more sensitive at higher temperatures than those which use the Lyman continuum only (504 Å < λ < 912 Å).

3. In exploiting the similarity of the He I and He II photoionization cross-sections, we are able to measure the presence of all but bare helium, which allows us to estimate the total hydrogen column density, not only that of neutral hydrogen, through an abundance argument (Equation (4)).

4. The images used here are co-temporal or nearly co-temporal, allowing us to combine EUV image data in a way that has previously only been possible with spatially rastering or fixed-slit spectrometer data.

5. When applied to erupting filaments in an expanding cavity, the complication of emissivity blocking is removed, as the
cavity rapidly expands to encompass the observed area including $I_0$ (but see below for a comment on this).

6. Material from an erupted filament is likely to also be several scale heights into the corona, meaning that the majority of emission will be from behind the erupting material, as suggested by Figure 4.

7. The method is, in principle, also applicable in a spatial-interpolative way.

A qualification of point 5 is that emissivity blocking can be understood as low-temperature material replacing higher-temperature plasma that would otherwise contribute to the emission seen by AIA. In this sense, it is not limited to prominence cavities, and could in fact lead to some overestimation of the absorption due to the filament, since the absorption depth is a measure of the decrease in intensity. However, since the filament material we have studied is likely to be rather high in the atmosphere, this consideration is unlikely to be important here.

Heinzel et al. (2008) draw an interesting (but probably incorrect) distinction between two types of observations previously used to carry out this type of analysis: those typically only obtained at one wavelength by large-field of view instruments (“patrol-type”); and those that use a combination of as many spectral lines as possible, termed “multi-wavelength” observations, largely performed by a superset of the authors in Heinzel et al. (2008) and Kucera et al. (1998). Perhaps because of the lack of co-temporal multi-wavelength data at the time, their definition of “multi-wavelength” refers to spectrometer observations, rather than images. We argue that the terminology is no longer valid since our method, which we term “polychromatic opacity imaging,” uses the patrolling advantages of a full-time, full-Sun imager, in combination with the (near-)co-temporal images from multiple passbands in the photoionization continuum to construct column density maps of large-scale features. Whereas contemporary EUV spectrometers are nearly always rastering, the examples we present have spatial simultaneity and can therefore be applied to large-field observations.

The results of fitted $N_H$ shown in Figure 9 reveal a surprising amount of coherence in their detail, and this may reflect agreement with a prior test carried out by Gilbert et al. (2005). These authors compared the results of spatial- and temporal-interpolative approaches where possible, and found that the temporal-interpolative approach yields more accurate (and precise) results when compared with Thomson-scattering estimates.
Lastly, our approaches have been restricted to narrower fields of view in this article, but this is largely driven by the desire to test the techniques. In principle, the methods can be applied to full-disk images. **SAO/AIA** is well suited to this task, and the current rise toward solar maximum would suggest many suitable targets for the method.

6. CONCLUSIONS

We present a study that shows the powerful application of polychromatic opacity imaging to cotemporal and near-cotemporal data from **SAO/AIA** of a spectacular filament eruption. The single- and multi-passband approaches used in this study give consistent lower limits on the total hydrogen column density (as opposed to just the neutral hydrogen column density) in the temperature regime below full ionization of helium, and therefore are sensitive to a large range in prominence temperature. The values of column hydrogen density that we find are larger than in previous studies, but one of the targets chosen is rather exceptional and perhaps large column masses are to be expected.

We restrict our study to estimating the column density and inferring the volumetric density of hydrogen. While this method does not address the issue of volume (or emissivity) blocking, which may be an effect for lower-lying prominence material (Gilbert et al. 2005; Anzer et al. 2007), it removes the need for coordinated observing campaigns to study prominence mass through comparison of opacity at multiple wavelengths. Using AIA data allows us to perform such studies of erupting filaments wherever they are observed.

Such observational constraints may be useful in the future development of more realistic models of erupting filament mass in coronal mass ejections.

D.R.W. acknowledges a UCL University Fellowship and D.R.W., D.B. and L.v.D.G. all acknowledge an STFC Rolling Grant, for the funding of this research. L.v.D.G. acknowledges funding through the Hungarian Science Foundation grant OTKA K81421. The research leading to these results has received funding from the European Commission’s Seventh Framework Programme under the grant agreement no. 284461 (eHEROES project). The authors also acknowledge the JHelioviewer team (Müller et al. 2009) for enabling fast searching of the data used in this study. JHelioviewer is part of the ESA/NASA Helioviewer Project. D.R.W. thanks Sarah Matthews, Lucie Green, David Brooks, and Nicolas Labrosse for valuable discussion on aspects of this work, and the referee for thoughtful comments and advice on the article.
