Abstract

Background: Tryptophan-pathway genes that exist within an apparent operon-like organization were evaluated as examples of multi-genic genomic regions that contain phylogenetically incongruous genes and coexist with genes outside the operon that are congruous. A seven-gene cluster in Xylella fastidiosa includes genes encoding the two subunits of anthranilate synthase, an aryl-CoA synthetase, and trpR. A second gene block, present in the Anabaena/Nostoc lineage, but not in other cyanobacteria, contains a near-complete tryptophan operon nested within an apparent supraoperon containing other aromatic-pathway genes.

Results: The gene block in X. fastidiosa exhibits a sharply delineated low-GC content. This, as well as bias of codon usage and 3:1 dinucleotide analysis, strongly implicates lateral gene transfer (LGT). In contrast, parametric studies and protein tree phylogenies did not support the origination of the Anabaena/Nostoc gene block by LGT.

Conclusions: Judging from the apparent minimal amelioration, the low-GC gene block in X. fastidiosa probably originated by LGT at a relatively recent time. The surprising inability to pinpoint a donor lineage still leaves room for alternative, albeit less likely, explanations other than LGT. On the other hand, the large Anabaena/Nostoc gene block does not seem to have arisen by LGT. We suggest that the contemporary Anabaena/Nostoc array of divergent paralogs represents an ancient ancestral state of paralog divergence, with extensive streamlining by gene loss occurring in the lineage of descent representing other (unicellular) cyanobacteria.

Background

Lateral gene transfer
Lateral gene transfer (LGT) has been generally accepted for some time, as exemplified by the endosymbiotic hypothesis of organelle origin [1,2]. Nevertheless, a long-standing background of general conviction has held that LGT is rare, especially between distant organisms. However, the modern era of genomics has been accompanied by increasingly numerous claims that LGT is frequent [3-6], and there now seems little doubt that LGT exerts a significant influence...
upon evolutionary histories. Indeed, it has even been asserted that vertical evolutionary patterns of descent might be impossibly masked by rampant events of LGT and that, in fact, instead of bifurcating phylogenetic trees, a reticulate (net-like) pattern exists [7-9]. On the other hand, others urge a more balanced perspective, pointing out that alternative explanations for apparent cases of LGT have not always been considered [10-14]. The rationale for explanations other than LGT for genealogical incongruities (such as hidden paralogies and reconstruction artifacts) have been presented in comprehensive detail by Glansdorff [15].

Woese [16] contends that the rRNA tree is a valid representation of organismal genealogy, that LGT was rampant only before the initial bifurcation of the universal phylogenetic tree, and that LGT has become progressively more restricted as a function of elapsed evolutionary time. Using the aminoacyl-tRNA synthases as an example of the modular-type entities asserted to be most amenable to LGT, Woese concludes that the genealogical trace of vertical gene flow is readable, despite a significant jumbling influence of LGT. If correct, this allows the optimistic viewpoint that the complex interplay of vertical gene descent and LGT can be deciphered to yield correct evolutionary histories, provided that sufficiently detailed studies are done.

Approaches for detection of LGT events are either phylogenetic or parametric. Phylogenetic approaches depend on congruence of phylogenetic trees. Aside from technical difficulties of inferring high-quality trees, conflicts between trees under comparison are not necessarily due to LGT, but can arise from coincidental loss of divergent paralogs in different, widely spaced lineages or from convergent evolution. Parametric approaches for detection of LGT include (but are not limited to) the analysis of nucleotide composition, dinucleotide frequencies and codon usage biases. Lawrence and Ochman [17] used such parametric analysis to identify a set of Escherichia coli genes (17.5% of the genome) having putative origin by LGT, and this has stimulated much discussion. High rates of both false positives and false negatives have been asserted by others [18,19], but this is tempered by presentation of a rationale for why phylogenetic and different parametric methods detect different gene subsets [20-22]. A consensus seems to be emerging that the most proficient attempts to reconstruct evolutionary events will employ a multifaceted approach that combines tree inference with parametric analysis in a biological context [21,22]. Lawrence and Ochman [21] provide a number of examples of how the context of biological information can assist the analysis, and this approach is implemented herein.

If each member of a linked group of genes is already represented elsewhere in a genome, their origin by LGT is a distinct possibility, as their transfer en bloc as an operon unit would have required only a single evolutionary event. During an ongoing analysis of the genomic distribution of tryptophan-pathway genes, we observed two such cases, that is, where one set of genes was phylogenetically congruent, in contrast to the incongruence of redundant gene copies that were linked to one another. We have evaluated the evidence for the alternative possibilities of LGT or ancient paralogy, as reported here.

A block of Trp-pathway genes in Xylella
The phylogenetic incongruence of trpR, a regulatory gene in Xylella fastidiosa, led to recognition of a low-GC gene block in X. fastidiosa. The tryptophan repressor (TrpR) is quite limited in its phylogenetic distribution, being consistently present only within the enteric lineage, as shown in the protein tree of Figure 1. Here TrpR of Sheuanaella putrefaciens marks the outlying sequence of the enteric lineage (shown in gray). Outside the boundaries of the enteric lineage, only Coxella burnetti, X. fastidiosa and two chlamydial species are thus far known to possess trpR. The distribution of trpR in the later three lineages is phylogenetically incongruent because they are widely spaced from one another on the 16S rRNA tree.

In Chlamydia trachomatis and Chlamyphila psittaci, trpR is positioned near structural genes of tryptophan biosynthesis, but no indication of recent origin by LGT of genes in this region was obtained [23]. X. fastidiosa trpR is separated by three genes from two structural genes of tryptophan biosynthesis. These latter genes do not appear to be essential for the primary task of tryptophan biosynthesis as all seven genes of tryptophan biosynthesis are represented elsewhere in the genome within one of two operons. Thus, in X. fastidiosa the incongruous phylogenetic position of trpR, the redundancy of the trp-linked genes encoding trpAa and trpAb, and the distinct phylogenetic incongruence of the latter gene pair all supported a reasonable possibility of origin by LGT.

The tryptophan supraoperon of Anabaena/Nostoc
All cyanobacteria possess each of the seven Trp-pathway genes at dispersed loci, and individual trees of proteins corresponding to these dispersed genes are phylogenetically congruent. Although this generalization also applies to Anabaena/Nostoc, this latter lineage is unique among cyanobacteria in its possession of an additional set of Trp-pathway genes (lacking only trypC) that coexist within an apparent operon. As shown in Figure 2, both Anabaena and Nostoc exhibit the same relative order of operonic trp genes: trpAa•trpAb • trpD → trpEa → trpEb → trpB. trpAa and trpAb are fused, as indicated in Figure 2 with a filled bar and in the text by the bullet in the notation: trpAa•trpAb. In Anabaena, qor (encoding NADPH: quinone reductase) has been inserted between trpD and trpEa. Another qor paralog is present elsewhere in the genome of Anabaena. Nostoc also has two qor paralogs, but neither resides within the tryptophan operon. Other cyanobacteria lack qor homologs altogether. In Nostoc, tyrP1 (encoding tyrosinase) has been
inserted between trpEa and trpEb. All other cyanobacteria, including Anabaena, lack tyrP. The two trp operons are less compact than frequently observed elsewhere, and relatively large intergenic spacing exists, especially in N. punctiforme. The only instance of translational coupling is between trpAa•trpAb and trpD in N. punctiforme.

The tryptophan operons appear to be nested within what could be a larger unit of transcription that is reminiscent of what has been called a supraoperon in Bacillus subtilis [24]. The genes comprising the supraoperon of B. subtilis are aroG → aroB → aroH → trpAaBDCEbEa → hisHb → tyrA_p → aroF. A hierarchy of internal promoters and terminators exists for differential control of the B. subtilis supraoperon. The Anabaena/Nostoc linkage group is additionally reminiscent of the B. subtilis supraoperon in the presence of aroB and tyrA. Although B. subtilis does not have aroA_I represented in its supraoperon (as do Anabaena and Nostoc), aroA_I is the homology class (of three possible DAHP synthase homologs distributed in nature [25-27]) that is utilized by B. subtilis. A number of supraoperon gene insertions have occurred outside of the trp operon as well. These differ for Anabaena and Nostoc as depicted in Figure 2. Anabaena has genes encoding aph and a hypothetical gene (open reading frame (ORF)) inserted between aroB and the trpAa•trpAb fusion. The aph gene encodes an uncharacterized protein of the defined alkaline phosphatases (metalloenzyme superfamily) (group COG1524 in the COGS database). Among cyanobacteria, only Nostoc has homologs of these two Anabaena genes, although they are not inserted in the Nostoc supraoperon. Nostoc has frnE (encoding a thiol-disulfide isomerase) inserted between tyrA_p and aroB.

Figure 1
Protein tree for TrpR. Bootstrap values are shown at internal branch positions as percentages (1,000 replicates).
Four subclasses of tyrA are defined according to the substrate specificities of the TyrA gene product: tyrAβ, specific for prephenate; tyrAγ, specific for arogenate; and tyrAϕ, accepts either prephenate or arogenate; and tyrAϕ, has broad specificity but exhibits a distinct preference for prephenate. Among all cyanobacteria, only Nostoc possesses frnE.

In their genomes outside the supraoperon boundaries, Nostoc and Anabaena possess a full complement of genes for biosynthesis of tryptophan, tyrosine and phenylalanine. Even these extra-supraoperonic genes of the Anabaena/Nostoc lineage are represented by multiple paralogs in many cases (Figure 2). If one considers the single-copy assemblage of aromatic-pathway genes present in the Synechocystis/Synechococcus/Prochlorococcus lineage as a fundamental complement of genes common to all cyanobacteria, the Anabaena/Nostoc genomic repertoire contains substantial redundancy. Thus, Anabaena has two additional extra-operonic paralogs of aroAϕ and trpD. In addition to extra-operonic, free-standing copies of trpAa and trpAb, a second fused gene (trpAϕ,trpAb_2) encoding the two domains of anthranilate synthase is present in Anabaena. Nostoc has two extra-operonic copies of aroAϕ, aroB and trpD. All cyanobacteria possess AroA of the Iβ class (aroAϕ). While this is also true of the Anabaena/Nostoc lineage (in fact, having multiple copies), both Anabaena and Nostoc possess an additional gene encoding AroA of the Iα class (aroAα). All cyanobacteria possess a tyrA gene of the arogenate-specific class (tyrAϕ), but the Anabaena/Nostoc supraoperons also possess a tyrA ϕ gene deemed to be a cyclohexadienyl dehydrogenase [28] with a favored specificity for prephenate (tyrAϕ) (C.A.B., R.A.J., N.K. and McNally A., unpublished observation).

Figure 3 shows an evolutionary scenario, using a Fitch diagram [29], that depicts the suggested origin of trpD paralogs via two gene duplication events (Dp1 and Dp2) that preceded the node of speciation divergence (Sp4) to Nostoc (Npu) and Anabaena (Asp). Consistent with the latter conclusion, Npu TrpD_1 exhibits greater identity with its ortholog Asp TrpD_1 than with its paralogs Npu TrpD_2 and Npu TrpD_3.
Results and discussion
Lateral gene transfer of a block of genes in Xylella

The trpR gene in X. fastidiosa was previously noted [23] to have anomalously low GC content, relative to that of the genome. Low-GC blocks of genes have been attributed to LGT before, for example, argF (present in E. coli K-12 but not in other strains) is bracketed with unidentified high-GC (59%) genes that together comprise a distinctive block of LGT genes [30]. The flanking genes of trpR were accordingly analyzed for GC content. Figure 4 shows that trpR in X. fastidiosa is at one end of a block of seven genes, all of which have a distinctively low GC content (highlighted in green), compared to the flanking genes (highlighted in yellow).

If the block of low-GC genes in Xylella really reflects an alien origin, differences in dinucleotide frequencies might be expected, as such context biases differ from organism to organism. A 3:1 dinucleotide bias (third nucleotide position in a codon analysis algorithm followed by the first nucleotide position in the succeeding codon) was utilized, as it is the dinucleotide that is least restricted by amino-acid preference and codon usage in individual genes [31]. The 3:1 dinucleotide frequencies were calculated for the entire block of low-GC genes, as well as for the immediately flanking genes. These results presented in Figure 5 with a set of four selected dinucleotides shows that dinucleotides frequencies of the flanking genes were within a variance of about 4% from genomic frequencies, whereas the low-GC block of genes exhibited recognizably greater variances from the genomic dinucleotides frequencies of X. fastidiosa.

The co-variation of 3:1 dinucleotide frequencies of genes in the low-GC gene block of Xylella with the corresponding genomic frequencies was also evaluated using the Spearman rank correlation coefficient. Table 1 illustrates the data used to compare the Xylella trpR gene and the Xylella genome. A p-value of 0.730 indicated that the 3:1 dinucleotide frequencies of trpR from Xylella did not exhibit significant co-variation with the frequencies of the Xylella genome. In contrast, the 3:1 dinucleotide frequencies of trpR from Chlamydia trachomatis did exhibit significant co-variation with the frequencies characteristic of the C. trachomatis genome (p-value = 0.031). These analyses are consistent with occurrence of recent LGT in X. fastidiosa.

What is the origin of the LGT gene block?

Gene organization is subject to constant change. For precisely this reason, the overall gene organization within the low-GC gene block might implicate a donor organism because the LGT event is inferred to be recent. Because the enteric lineage is a reasonable source of the LGT gene block, it is pertinent that the gene organization around trpR is highly conserved in the enteric lineage. Without exception, trpR in the enteric lineage is preceded upstream by a gene encoding soluble lytic murein transglycosylase (slt). hemK is usually positioned directly downstream,
except for the *Haemophilus actinomycetemcomitans/H. influenzae/Pasteurella multocida* grouping (where the downstream gene encodes a monofunctional biosynthetic peptidoglycan transglycosylase (*mtgA*)). No genomes of the enteric lineage were found to possess *trpR* in a context of flanking genes that resembled the *X. fastidiosa* gene organization.

The LGT-block of *Xylella* genes conceivably could have originated from a donor similar to a common ancestor of the chlamydiae before the massive gene reduction associated with the chlamydial lifestyle. This would be consistent with the low GC content of both the chlamydial genome and the LGT-block of genes, as well as with the observation that chlamydiae and *Xylella* are the only two known taxa where *trpR* is positioned near structural genes of the tryptophan pathway. Direct comparison of chlamydial *trpAa* and *trpAb* genes with those of the *Xylella* operon is not possible because all chlamydial genomes thus far mapped lack *trpAa* and *trpAb* [23]. In this context, sequencing of genomes from closely related free-living relatives of the chlamydiae could be informative. The currently available chlamydial genomes also lack other genes of the low-GC block.

*C. burnetii* was also considered as a possible source of the low-GC gene block in *X. fastidiosa* because it possesses *trpR*. This potential LGT event seems ruled out because *trpR* is not near any structural genes encoding TrpAa and TrpAb in *C. burnetii*; *C. burnetii* TrpAa and TrpAb are not close to the corresponding *X. fastidiosa* enzymes on phylogenetic
trees; and *C. burnetii* lacks the remaining genes in the low-GC gene block of *X. fastidiosa*.

If LGT accounts for the low-GC gene block in *X. fastidiosa*, how recent was this event? Presumably, it was sufficiently recent that significant amelioration to the genomic GC content has not yet occurred. The closest sequenced genome to *Xylella* is *Xanthomonas*. Genomes representing two species of the latter genus have been sequenced, and both lack the low-GC gene block. Therefore, the putative LGT event occurred some time after lineage divergence of *Xylella* and *Xanthomonas*. On the other hand, LGT presumably has predated speciation in the *Xylella* genus as all three strains of *Xylella* in the National Center for Biotechnology Information (NCBI) database possess the low-GC gene block. The latter genes are located within either of two separate operon clusters (Figure 6) with the GC content characteristic of *X. fastidiosa*. The GC-content values for the latter genes: *trpAa*, *trpAb*, *trpAbC*, *trpD*, *trpEa*, and *trpEb* are 52%, 49%, 54%, 55%, 51%, 59% and 55%, respectively. Furthermore, Figure 6 shows that the organization of the full complement of *trp*-pathway genes into two operons in *X. fastidiosa* is similar or identical to that of some of its nearest neighbors on the 16S rRNA tree, although the *Xylella* operons exhibit atypically large intergenic spacings. None of these neighbors possesses the low-GC block of *Xylella* genes illustrated in Figure 4. Hence, the two operons shown in Figure 6 can be inferred to be responsible for primary tryptophan biosynthesis throughout this clade.

Genes encoding the two anthranilate synthase subunits (*trpAa* and *trpAb*) and aryl-CoA ligase (*acl*), and the CoA ligase are apparently located in the same operon (Figure 5). This operon exhibits strong similarity to coenzyme F390 synthetase of methanogenic archaea, as well as to phenylacetate-CoA synthase (Figure 4). These probably do not function for general tryptophan biosynthesis since paralogs of these genes, which exhibit a phylogenetically congruent context of gene organization, exist elsewhere in the genome (Figure 6).

**What is the function of the low-GC block of genes in Xylella?**

Within the low-GC block, *trpR* is separated by four ORFs from genes encoding the two subunits of anthranilate synthase (*trpAa* and *trpAb*). These probably do not function for general tryptophan biosynthesis since paralogs of these genes, which exhibit a phylelogenetically congruent context of gene organization, exist elsewhere in the genome (Figure 6).

**Figure 5**

Three-to-one dinucleotide analysis of the putative LGT-block of *X. fastidiosa* genes shown in Figure 4. For easier viewing, four of the 16 dinucleotide combinations have been selected. The frequency variation of each gene is shown as positive variation (upward-pointing bars) or negative variation (downward-pointing bars) with respect to the average genomic frequencies (set to a value of zero at the midline), the absolute values of which can be seen in Table 1. treg, transcriptional regulator; hypo, hypothetical gene.
ligase of *E. coli*. As *Xylella* does not appear to make the F420 cofactor that is the substrate of F390 synthetase, the function of Acl is likely to be closer to phenylacetate-CoA ligase. The aromatic ring is highly stable, and CoA thioesterification can provide chemical activation, allowing cleavage of the aromatic ring, as exemplified by catabolism of benzoate, 4-hydroxybenzoate, and anthranilate [32]. Because acl is tightly organized with *trpAa* and *trpAb*, it seems feasible that anthranilate might be the substrate of acl. An anthranilate-CoA ligase has been described recently in *Azoarcus evansii* by Schühle et al. [33]. The *Xylella* Acl exhibited greater identity with phenylacetate-CoA ligase of *E. coli* than with anthranilate-CoA ligase of *A. evansii*, but a given substrate specificity within homology groups often can be associated with different subgroupings [25, 34].

If anthranilate is indeed the substrate of acl in *Xylella*, it would be a futile cycle if anthranilate were formed biosynthetically, only to be subsequently catabolized. Therefore, it seems more likely that the activation of anthranilate could be a step in the formation of a siderophore or antibiotic compound that is assembled by a nonribosomal peptide synthetase mechanism (see Quadri et al. [35] and references therein for numerous examples). Pyocelin from *Pseudomonas aeruginosa* exemplifies an iron siderophore whose peptide-based synthesis depends on CoA-activated salicylate (closely related to anthranilate) as a starter unit [36].

While it appears likely that *trpR*, aryl-CoA ligase, *trpAa* and *trpAb* belong to a common functional unit, the possible roles of the remaining three genes downstream of acl are problematic at the present time.

The *Anabaena/Nostoc* gene blocks

The large gene blocks in *Anabaena* and *Nostoc* that begin with *aroA* and end with *tyrA* exhibited GC ratios that were similar to that of the host genome (Table 2). This is not necessarily inconsistent with their possible origin by LGT because the GC ratio of a putative donor genome could have been coincidentally similar to that of *Anabaena* and *Nostoc*.

Accordingly, the 3:1 dinucleotide frequencies of the *aroA*-*tyrA* gene block and the immediately flanking genes were analyzed, but these dinucleotide frequencies also did not suggest LGT. Figure 7 shows that dinucleotide frequencies did not deviate more than 5% from the genomic frequencies across the *aroA*-*tyrA* gene block. This contrasts with the distinctly greater deviation of 3:1 dinucleotide frequencies within the low-GC gene block of *Xylella*, which is shown on the same scale as the *Anabaena* data.

Codon usage was analyzed throughout the gene block and also failed to implicate LGT. Figure 8 exemplifies this with a comparison of the pair of TrpAa domains in *Anabaena*, one encoded from within the gene block and the other outside. As *Xylella* also possesses a TrpAa pair, one encoded from within the low-GC gene block and the other outside, the analyses of these are also included in Figure 8 as a kind of positive control. In *Anabaena* (two bars on the right of each panel) the codon usage for leucine, serine, arginine, glycine, valine and proline was very similar for the TrpAa domain of *Anabaena* and the immediately flanking genes were similar to that of the host genome (Table 2). This is not necessarily inconsistent with their possible origin by LGT because the GC ratio of a putative donor genome could have been coincidentally similar to that of *Anabaena* and *Nostoc*.

**Table 1**

**Statistical test of co-variation of 3:1 dinucleotide frequencies of trpR and its cognate genome**

Analysis of protein trees

We evaluated whether the closest BLAST hits, using as queries the amino-acid sequences corresponding to the operonic genes of *Anabaena* or *Nostoc*, would be with other cyanobacteria (and therefore consistent with origin by gene duplication) or with another taxon grouping (consistent with LGT). In either case, one would expect that the sequences encoded by the operonic genes of *Anabaena* would be the best matches for the operonic genes of *Nostoc*, as was indeed
constructed for each by examination of extensive trees (available upon request). Cyanobacterial lineage origin was confirmed more rigorously presented proteins of or clustered together, regardless of whether they were For the Trp-pathway proteins, all the cyanobacterial proteins denoted TyrAa) of the superfamily. The additional TyrA(p) present only in Anabaena and Nostoc and located as the carboxy-terminal gene of the supraoperon exhibits identities of 39-43% with the TyrA(p) proteins of some enteric bacteria. These results for supraoperonic aroB and tyrA(p) could be consistent with LGT, but with no clear donor candidates available. On the other hand, origin as ancient paralogs is also a possibility.

**The trpAa•trpAb fusion**

A particularly fortuitous gene that could favor or disfavor the hypothesis of LGT of the aroA(p)-tyrA(p) gene block in Anabaena/Nostoc is trpAa•trpAb, a fusion corresponding to two genes that are usually separate (free-standing). As only a limited number of trpAa•trpAb fusions are known, possible LGT donors can be evaluated. Organisms known to possess the trpAa•trpAb fusion are listed at the top of Table 3. Another small group of trpAa•trpAb fusions are known, which are dedicated to phenazine biosynthesis and which form a distinct cluster. These are denoted trpAa•trpAb_phz in Table 3. Thus far, the trpAa•trpAb_phz fusions are limited to species of Pseudomonas and Streptomyces. pabAa and pabAb are homologs of trpAa and trpAb, and the distribution of fusions involving these domains are also listed in Table 3 to give a general sense of the frequencies of such gene fusions. A variety of data (G.X. and R.A.J., unpublished observation) indicates that equivalent fusions often arise independently of one another in widely spaced lineages.

---

**Figure 6**

Organization of trp-pathway genes in X. fastidiosa and its nearest phylogenetic neighbors. The position of the organisms indicated on a 16S rRNA subtree is shown at the far left. To enhance the presentation, the trp-gene acronyms are shortened. Thus, trpAa is shown as Aa, etc. Intergenic spacing is indicated. dmt refers to a putative DNA methyltransferase. TrpAa in Nitrosomonas europaea and trpC in Bordetella parapertussis are located in other chromosomal positions, unlinked to other trp-pathway genes. X. fastidiosa and N. europaea, but not the other organisms shown in the figure, possess truA (encoding tRNA pseudouridine synthase A) upstream of trpC. truA and trpC are translationally coupled with 31-bp overlaps in X. fastidiosa and N. europaea, respectively. The gene organizations shown for a given organism is identical to the other organisms shown in parentheses as follows: *Ralstonia metallidurans* (R. solanacearum), *Bordetella fungorum* (B. pseudomallei, B. mallei), and *B. parapertussis* (B. pertussis, B. bronchiseptica). *R. solanacearum*, in addition to the genes shown, has adjacent paralogs of trpB and trpD located on a large plasmid. The trpAaBBD and trpCEBa operons of the *X. fastidiosa* 9a3c genome correspond to gene numbers XF0210-XF0213 and XF1374-XF1376, respectively.

<sup>a</sup> Anabaena sp. PCC 7120 has a genomic GC ratio of 42.82%. <sup>b</sup> Nostoc punctiforme has a genomic GC ratio of 43.90%.

Figure 9 shows a segment of the 16S rRNA tree that contains all of the trpAA•trpAB fusions which are known so far. Cyanobacteria other than Anabaena/Nostoc lack the fusion, as do all nearby lineages. The fusion is present in the cluster that includes Rhodopseudomonas palustris, Rhizobium loti, Brucella melitensis, Agrobacterium tumefaciens and Sinorhizobium meliloti. (A. tumefaciens, which is not shown in Figure 9, is virtually identical to S. meliloti). Additional phylogenetically spaced fusions are present in Thermomonospora fusca, Azospirillum brasilense, and Legionella pneumophilia. Other fusions that involve trpAA or trpAB homologs also occur in nature, as shown in Table 3, and a degree of care is needed to avoid confusion between them.

A phylogenetic tree consisting of all free-standing TrpAa and TrpAb proteins was constructed, together with the corresponding two domains of the TrpAa•TrpAb fusions (available upon request). Surprisingly, each of the 10 fusion domains clustered tightly on the TrpAa and TrpAb trees, to the exclusion of the free-standing TrpAa and TrpAb domains. This is consistent with a single ancestral fusion event, but requires the assumption of multiple LGT events. However, it is surprising that no free-standing domains (that is, close homologs of the original fusion partners) cluster with either of the two sets of 10 fusion domains. This might suggest an alternative to LGT, namely that there has been extreme sequence convergence because of strong selection for appropriate residues mediating domain-domain interactions. If so, it is possible that trpAA•trpAB fusions occurred as a number of independent events, followed by strong convergence.

Figure 9 shows the individual genomic organization of trp-pathway genes in the 16S rRNA tree sector that is relevant to the trpAA•trpAB fusion. The Anabaena/Nostoc lineage is unique in having trpAA•trpAB linked to other trp-pathway genes and is further unique in having an additional set of free-standing genes encoding TrpAa and TrpAb. Although generally uncommon, complete dispersal of Trp-pathway genes is characteristic of the non-filamentous cyanobacteria, *Aquifex aeolicus* and *Chlorobium tepidum*. The ancestral state of trp gene organization has been asserted (G.X., C.B., N.K. and R.J., unpublished work) to be trpAA/Ab/B/D/C/Eb/Ea, an operon organization seen in contemporary *Cytophaga hutchinsonii*, *Desulfovibrio vulgaris* and *Coxiella burnetii* (Figure 9). Dynamic gene reorganization events that involve gene insertions, gene scrambling, gene duplications and gene dispersal are apparent from inspection of Figure 9.
It is expected that LGT would most easily be recognized if it occurred relatively recently before passage of sufficient time for amelioration of alien characteristics to those of the host genome, for example GC content. In the case of each of the known \textit{trpAa}•\textit{trpAb} gene fusions, the absence of the gene fusion in a closely related genome implies that the gene-fusion

*Also known as phzE. †pabAa, pabAb and pabAc are also known as pabB, pabA and pabC.

If any of the trpAa•trpAb fusions, other than the Nostoc/Anabaena pair, have a common origin, similar flanking regions of gene organization might be expected since all of the fusions are of relatively recent origin. On this criterion, only R. loti, B. melitensis, A. tumefaciens and S. meliloti exhibited similarities of flanking-gene organization, and this is phylogenetically congruent. These observations imply that within the span of phylogeny shown in Figure 9, the trpAa•trpAb fusion may have occurred independently as many as seven times.

Interdomain linker regions

In fusion proteins an interdomain linker region of critical length and mobility is important to facilitate specific domain-domain interactions. Fusions of independent origin might be expected to exhibit a variety of linker regions. Particular constraints undoubtedly limit this variety, and such constraints might be more stringent for some domain combinations than others. (In the case of particularly stringent constraints, similar linker regions would not necessarily demonstrate a common origin). Figure 10 shows an alignment of the carboxy-terminal region of the TrpAa domain, the linker region, and the amino-terminal region of the TrpAb domain for all of the fusion proteins depicted in Figure 9 (as well as that from A. tumefaciens).

Only the two operonic fusion proteins from Anabaena and Nostoc and the four rhizobial fusion proteins (Mlo, Bme, Rme and Atu) exhibit linker regions of identical length and obvious similarity. The paralog TrpAa•TrpAb protein of Anabaena sp (Asp_2) seems to have a distinctly different linker, and it may be that the two fusions in Anabaena arose as two independent events. The partial sequences shown in Figure 10 are spaced to indicate the seven independent events of gene fusion that are suggested.

Function of the Anabaena/Nostoc gene blocks?

The gene blocks shown in Figure 2 encode the entire tryptophan pathway (except for trpC), as well as the first two enzymes of the common aromatic pathway, and the key enzyme of tyrosine biosynthesis. Multiple enzymes catalyzing the same reaction have been described in developmental systems where differential regulation of isoenzymes are deployed in different temporal and spatial contexts. Filamentous cyanobacteria (such as Anabaena and Nostoc) subscribe to a developmental program of heterocyst formation that is widely considered the primitive state and that correlates with their exceedingly large genomes. Unicellular cyanobacteria such as Synechocystis, Synechococcus and Prochlorococcus have far smaller genomes and lack the ability to fix nitrogen (heterocyst formation). It, therefore, seems to be a distinct possibility that the gene blocks diagrammed in Figure 2 (as well as additional gene duplicates) are specifically involved in specialized capabilities of Nostoc/Anabaena that do not exist in other cyanobacteria. In terms of the evolutionary scenario, the Anabaena/Nostoc lineage may reflect the
**Figure 9**

16S rRNA tree showing the phylogenetic distribution (highlighted in yellow) of trpAa-trpAb fusions. The gene fusions unlinked to any other trp genes are shown to the right of the highlighted name. The remaining trp-operon gene organizations are shown at the right. The white arrows indicate gene insertions that encode the following: *Thermomonospora*, integral membrane protein; *Streptomyces*, three membrane proteins: *Corynebacterium*, membrane protein, pantoate β-alanine ligase (panC), and 3-methyl-2-oxobutanoate hydroxymethyl transferase (panB); *Mycobacterium*, conserved hypothetical protein; *Cytophaga*, conserved hypothetical protein; *Sphingomonas*, conserved hypothetical protein and outer-membrane protein; *Rhodobacter*, and acetyltransferase yibQ; *Ralstonia*, DNA methyltransferase (dmt); *Burkholderia*, DNA methyltransferase (dmt). In addition *aroR* in *R. sphaeroides* is a putative regulatory gene [58]. The lineage relationships of three organisms that have maintained the putative ancestral trp operon are shown with heavy, gray lines.
ancestral state, and modern unicellular cyanobacteria may be derived genomes that are smaller and more streamlined (reductive evolution).

**Conclusions**

**Operon displacement**

Alien genes that may be subject to possible LGT can generally expect a hostile reception in that they lack a history of functional integration with the resident genome. Genes that offer immediate selective advantages (for example, antibiotic resistance) are likely to persist. The acquisition of a completely new functional capability will often require an entire suite of novel genes, and such recruitment is certainly easier to envision if all of the genes arrive en bloc (that is, as an operon). Once a primary biosynthetic pathway, such as that responsible for tryptophan formation, has been established and integrated with the individualistic metabolic circuitry of a given organism, one does not expect facile displacement of resident genes. This should apply even if the incoming genes all coexist as an operon. We have found only two examples of LGT of whole-Trp operons, that of $trpAa/Ab/B/D+C/Eb/Ea$ from the enteric lineage to coryneform bacteria and to *Helicobacter*, as discussed earlier.

**Has there been separate lateral gene transfer of individual genes?**

According to the foregoing rationale, isolated genes that participate in multi-step processes would not generally be expected to have much success in LGT. In some cases analog genes encode enzymes that catalyze the same reaction in a multi-step pathway, and one analog gene might conceivably displace another. Lack of enough information about genomic representation of such analog genes can lead to incorrect inferences of LGT. For example, the initial discovery of “plant-type” AroAII in bacteria led to the assumption of LGT from plant to bacterium. Elucidation of the fuller genomic representation of such analog genes can pose great difficulties in distinguishing LGT from vertical transmission. Phylogenetic incongruities that involve such analogs can pose great difficulties in distinguishing LGT from vertical progressions of differential analog losses in different lineages.

**Specialized Trp genes not required for primary biosynthesis**

In this article we focus on a number of cases where at least several *trp* genes are linked, thus providing analytical advantages offered by the analysis of more than one gene. These genes are also redundant and phylogenetically incongruent, in contrast to coexisting homolog genes that are part of a full phylogenetically congruent set. Both of the latter are consistent with origin by LGT, but unrecognized ancient paralogy is also possible. In the first case, the homologs coexisting in one organism are xenologs, whereas in the latter case, they are paralogs. A relatively simple example is the *trpAa/trpAb* pair originally denoted *phnA/phnB* in *Pseudomonas aeruginosa* [39]. This comprises an anthranilate synthase that is

---

**Figure 10**

Comparison of *TrpAa*•*TrpAb* linker regions. The seven independent fusions that are suggested were aligned with free-standing *TrpAa* and *TrpAb* proteins in order to visualize the inter-domain linker regions. Amino-acid residue numbering is indicated at the left and right margins.
not strictly required for primary tryptophan biosynthesis and that is uniquely expressed during stationary-phase physiology [40]. Why the generation of anthranilate under these conditions would be of value is unknown, but phylogenetic trees clearly show phnA/phnB to be xenologs originating from the enteric lineage via LGT (G.X. and R.A.J., unpublished data). In this case, genes that function for primary biosynthesis in the donor genome did not displace the corresponding genes in the recipient genome, but have instead been recruited to a specialized function. In *Streptomyces coelicolor*, trpAa/trpAb/trpB/trpD/aroA_H are contained within a large cluster dedicated to antibiotic synthesis [41]. Calcium-dependent antibiotic (CDC) contains tryptophan, and presumably the feedback-resistant variety of enzyme encoded by aroA_H ensures enhanced precursor flow to tryptophan during antibiotic production. Detailed studies have not yet been done to see whether the CDC gene cluster originated via LGT or reflects ancient paralogy.

In this article, we have discussed at length the *Xylella* and cyanobacterial gene blocks that seem likely to have specialized functional roles other than primary biosynthesis. The *Xylella* genes are associated with other genes that presumably dictate a fate for anthranilate other than as a primary precursor of tryptophan. We suspect that selective advantages conferred by this specialized operon accommodated successful LGT to *Xylella*. The *Anabaena/Nostoc* supraoperon is reminiscent of the *S. coelicolor* system in the inclusion of AroA_H, which might enhance precursor flow to chorismate. Although the *Anabaena/Nostoc* operon only lacks trpC, its features of gene fusion and gene organization are novel. It might perhaps have an unknown physiological function related to the complex developmental programs unique to heterocystous cyanobacteria. We conclude that in this case the operonic trp genes are ancient paralogs of a dispersed set of trp genes engaged in primary biosynthesis.

Against a backdrop where organisms generally possess highly efficient and integrated pathways of tryptophan biosynthesis, displacement of resident genes by LGT of the corresponding genes is relatively infrequent. Aside from the broadly distributed primary pathway, highly specialized pathways are known that utilize some or all tryptophan-pathway enzymes, and these pathways can originate by recruitment of paralog genes derived from the primary-pathway genes [42]. The genes of such specialized operons may diverge considerably to meet the demands of a novel functional role. In a contemporary organism this might have the status of unrecognized (or recognized) paralogy, as we suggest for the *Anabaena/Nostoc* gene block. However, such an operon module also has strong potential for xenologous transfer because of its specialized functional potential.

The tryptophan pathway exemplifies the situation where paralogs can be engaged in primary amino-acid biosynthesis (widespread) or in a variety of specialized pathways (narrowly distributed). Aside from the extent to which the specialized pathways may be individually intriguing and important, this study illustrates that case-by-case analysis can distinguish paralogs (or xenologs) from their homologs engaged in primary biosynthesis. This conclusion is encouraging as it shows that both vertical and horizontal events of gene transfer can be deduced to track evolutionary history.

### Materials and methods

#### Dinucleotide frequencies

The CODONW program [43] was used to calculate 3:1 dinucleotide frequencies (third base of a given codon followed by the first base of the next codon). For whole-genome calculations, genome nucleotide sequences (.ffn file) were obtained from GenBank [44]. Perl scripts were used to eliminate the define and assemble all genomic ORFs together for CODONW calculation. The length (from UNIX wc command) divided by 3 was used to validate the absence of frameshift errors. Pairwise covariation of 3:1 dinucleotide frequencies was assessed by the Spearman rank correlation coefficient [45], a nonparametric rank statistic for testing monotonic relationships. T2 values were kindly provided by Hooper [31].

#### Codon usage

Codon usage for individual genes was computed with the CDONTREE program [46]. Codon-usage values for whole genomes were obtained from the Codon Usage Database [47,48].

#### Phylogenetic trees

16S rRNA subtrees were derived from the Ribosomal Database site [49,50]. Unrooted phylogenetic protein trees were derived by input of the indicated homolog amino-acid sequences into the ClustalW program (Version 1.4) [51]. Manual alignment adjustments were made as needed with the assistance of the BioEdit multiple alignment tool of Hall [52]. The refined multiple alignment was used as input for generation of a phylogenetic tree using the program package PHYLIP [53]. The neighbor-joining and Fitch programs [51] were used to obtain distance-based trees. The distance matrix was obtained using Protdist with a Dayhoff Pam matrix. The Seqboot and Consense programs were then used to assess the statistical strength of the tree using bootstrap resampling. Neighbor-joining and Fitch trees yielded similar clusters and arrangement of taxa within them. Bootstrap values indicate the number of times a node was supported in 1,000 resampling replications.

#### Identification of linker regions

Fusion proteins were aligned (ClustalW) with one another and with the assemblage of free-standing proteins corresponding to the amino-terminal and the carboxy-terminal domains of the fusion proteins. The boundaries of each domain were defined by the last highly conserved residues of...
the amino-terminal domain and the early highly conserved residues of the carboxy-terminal domain. The Conserved Domain Database was useful as a reference guide [54,55].

Comparative genome analysis
Most of the comparative genome analysis was carried out using the database and tools of ERGO [56].
