ABSTRACT

We derive the density profile of cold dark matter halos using a self-similar accretion model. We show that if the clumpiness of the infalling matter is taken into account, then the inner density slope, \( \delta = d \log \rho / d \log r \), is close to \(-1\). Compared with the density profiles predicted by different numerical simulations, we find that outside \( \sim 0.1\% \) of the virial radius, our solutions agree best with the fitting formula proposed by Navarro et al. (2004), \( d \ln \rho / d \ln r = -2(r/r_2)^\alpha \), \( \alpha \sim 0.17 \), where \( r_2 \) is a characteristic radius, inside which the density profile becomes shallower than isothermal (\( \delta < -2 \)).

Subject headings: cosmology: theory – dark matter – large-scale structure of Universe

1. INTRODUCTION

In the standard \( \Lambda \)CDM paradigm dark matter halos evolve out of small fluctuations in the initial density field. Since the structure of virialized objects may depend on their formation history, many attempts have been made to link the observed density distribution of dark matter halos with the initial spectrum of density fluctuation. High resolution N-body simulations indicate that density profiles of dark matter halos have a universal shape

\[
\rho(r) = \frac{\rho_s}{(cr/r_{vir})(1+cr/r_{vir})^2}
\]

whose dependence on the initial conditions is apparent only from the value of the concentration parameter \( c \) (Navarro, Frenk & White 1997; henceforth NFW). While the NFW model has been usually successful in reproducing the observed mass profiles of large galaxies and galaxy clusters, it seems to be inconsistent with the rotation curves of the dwarf galaxies. In addition, several other N-body simulations (e.g. Moore et al. 1999; Fukushige & Makino 2003; Ricotti 2003), while generally obtaining similar results at large radii, found different density slopes in the inner regions of halos, thus raising some doubts about the accuracy of the NFW model.

The alternative approach to N-body simulations is provided by analytic modeling and in particular by self-similar accretion models (Fillmore & Goldreich 1984; Bertschinger 1985). The choice of a particular set of initial conditions (a profile of an initial density perturbation is assumed to be a power law, \( \Delta M/M \propto r^{-3\epsilon} \)) allows to recover an exact analytic solution for the final density distribution, that can be compared to the N-body results. Further, it can be shown that the appropriate value of \( \epsilon \) (and therefore the final density profile) is fixed by the slope of the initial density fluctuations, \( \epsilon = (n+3)/6 \), where \( n(k) = d \log P(k)/dk \) (Peebles 1980). Unfortunately, the very simplicity that is a strong point of the analytic models, can also lead to their downfall, if an important physical process has been left out. Purely radial infall that results from the evolution of a spherically symmetric density perturbation, produces an extremely steep inner density profile, \( \delta = d \log \rho(r)/d \log r \lesssim -2 \). As neither the observations nor any of the N-body simulations produced a similarly steep density distribution, attempts have been made to fix the self-similar models by giving collapsing halos some initial angular momentum (White & Zaritsky 1991; Sikivie et al. 1997, Subramanian 2000, Nusser 2001). Including angular momentum allows to reduce the steepness of the inner slope, down to \( -9\epsilon/(3\epsilon + 1) = -3(9n + 9)/(n + 5) \). However, in general the solutions, being dependent on the amount of added angular momentum, still did not reproduce the universal shape given by equation (1).

In this paper we show that the discrepancy between the self-similar models and N-body simulations is naturally resolved by including the process of dynamical relaxation into the former. We prove that even tiny deviations from spherical symmetry are sufficient to make the dark matter particles velocity distribution isotropic in the inner region, provided the density slope is steeper than \(-1\). Furthermore, we show that for \( n < -1 \) (\( n < 1/6 \)) isotropic velocity distribution leads to the inner density slope \( \delta \sim -1 \). Since the spectral index, \( n(k) \), spans the range from \(-3 \) (for smallest halos) to \(-1 \) (for galaxy clusters), our results imply that if the dark matter gravity is the only force to be considered, then \( \delta \sim -1 \) in all existing virialized halos.

The paper is organized as follows. In §2, we show that density profiles, which are steeper than \( \rho \propto r^{-1} \), are inconsistent with unisotropic velocities at the central region. In §3, we derive a density profile for a self-similar accretion model that includes dynamical relaxation process. In §4, we compare our results with the N-body codes. We summarize our conclusions in §5.

2. DYNAMICAL RELAXATION

In the standard \( \Lambda \)CDM paradigm the structure formation is hierarchical. The smallest halos that form first subsequently merge into larger and larger objects. If dynamical friction between merging dark matter clumps is weak, clumpiness and radial orbits can be retained for a long time. On the other hand, if dynamical friction is strong, the clumps are destroyed and the velocities of dark matter particles become isotropic. As we show below, the latter is always the case at the central regions of halos with sufficiently steep (\( \delta > -1 \)) density profiles.

Consider a halo of mass \( M_h \) and radius \( R_h \) formed by smaller clumps with the typical mass \( m_{cl} \). The clumps characteristic relaxation time is

\[
t_{rel} \sim (\pi n_{cl} G m_{cl}^3 V_{cl}^{-3} \log(M_h/m_{cl})^{-1}),
\]

where \( n_{cl} \sim \rho/m_{cl} \) and \( V_{cl} \) are the clump number density and characteristic velocity. The kinetic energy of clumps must be
less than their potential energy at the center, $V_2^2/2 \lesssim GM_\Lambda/R_\Lambda$. This sets an upper limit on the relaxation time

$$t_{rel} \lesssim \frac{\sqrt{8M_\Lambda}}{\pi n_{crit} G^{1/2} m_{crit} R_\Lambda^{3/2} \log(M_\Lambda/m_{crit})}. \quad (3)$$

Since the radial infall velocity of a clump is less than $\sim \sqrt{2GM_\Lambda/R_\Lambda}$, the time required for a clump to reach the center from a distance $r$, $t_{cr}$, exceeds $r/\sqrt{2GM_\Lambda/R_\Lambda}$. For radial orbits to be sustained, the crossing time must be less than the relaxation time

$$1 < \frac{t_{rel}}{t_{cr}} \lesssim \left( \frac{4M_\Lambda^2}{\pi n_{crit} \log(M_\Lambda/m_{crit}) R_\Lambda^2} \right) [\rho r]^{-1}. \quad (4)$$

Obviously, if the density profile is steeper than $\rho \propto r^{-1}$, then close to the center (i.e. for small values of $r$) the above inequality would be violated, implying that in such a case dynamical friction must be strong and radial orbits cannot be sustained. Therefore, in the case where purely radial infall leads to a density slope below $-1$, dynamical relaxation must either isotropize the velocities or flatten the central density cusp to $\rho \propto r^1$.

3. SELF-SIMILAR INFALL

We now proceed to calculating the actual density distribution of the collapsing halos, including the dynamical relaxation process. In the Einstein-de Sitter model (which is an excellent fit at high redshifts) a system evolving from a power law density perturbation $(\Delta \rho/\rho \propto r^{-3})$ over a time approaches self-similarity, which allows to use dimensionless variables for mass profile, density, bulk velocity and energy density of dark matter particles.

$$m(r,t) = M(\lambda) \frac{2r^3}{9Gt^2}, \quad (5)$$
$$\rho(r,t) = D(\lambda) \frac{1}{6\pi Gt^2}, \quad (6)$$
$$v(r,t) = V(\lambda) \frac{r_{vir}}{t}, \quad (7)$$
$$p(r,t) = \Pi(\lambda) \frac{r_{vir}^2}{18\pi Gt^2}. \quad (8)$$

where $\lambda = \rho r_{vir}$ and $t$ is a Hubble time. The virial radius, $r_{vir}$, which is customarily defined as a radius inside which the density contrast is $18\pi^2 \approx 178$, grows as $t^n$, where $n = 2(3\epsilon + 1)/9\epsilon$.

At a fixed $\lambda$ the relaxation time (equation (4)) scales as $t$, which implies that the relaxation process does not break self-similarity. However, for the sake of simplicity, rather than evaluate the impact of dynamical relaxation on particle velocities at each point, we assume that at large radii the infall is purely radial, neglecting small tangential motions. Close to the center we assume that the velocities are completely isotropic. Furthermore, we assume that an abrupt transition between the two regimes occurs at some point. This transition is analogous to the shock heating of the infalling gas (though for collisionless dark matter the width of the transition region can be significantly larger than the width of the shock, which roughly equals baryon mean free path). This approach allows us to treat the dark matter as a dissipationless fluid whose dynamics is determined by continuity, Euler and adiabatic equations. Cast into the dimensionless variables, these equations become

$$\begin{align*}
(V-\eta\lambda)D' + \left(\frac{2V}{\lambda} + V - 2\right)D &= 0, \quad (9) \\
(\eta - 1)V + (V - \eta\lambda)V' &= -\Pi' \frac{2}{D} - \frac{2M}{9\lambda^2}, \quad (10) \\
\left(\frac{5D'}{3D} - \frac{\Pi'}{\Pi}\right)(V - \eta\lambda) &= 2\eta - \frac{2}{3}, \quad (11) \\
M' &= 3\lambda^2 D, \quad (12)
\end{align*}$$

If all non-adiabatic cooling and heating processes can be neglected, the above equations are equally applicable to the baryonic and dark matter fluids (Chuzhov & Nusser 2000).

Outside the shock the radial motion of the infalling matter can be traced analytically (Bertschinger 1985). The jump conditions at the adiabatic shock are

$$\begin{align*}
V^+ &= \eta\lambda V + \frac{V - \eta\lambda}{4}, \quad (13) \\
D^+ &= 4D^-, \quad (14) \\
P^+ &= \frac{3}{4}D^+(V - \eta\lambda)^2, \quad (15) \\
M^+ &= M^-, \quad (16)
\end{align*}$$

where the superscript minus and plus signs refer to pre- and post-shock quantities. The location of the shock, $\lambda_v$, which is initially unknown, have to be found by integrating equations (9-12) inwardly. Too small values of $\lambda_v$ produce a non-zero mass at $\lambda = 0$, while too large values of $\lambda_v$ give a singularity at some $\lambda > 0$. A unique value of $\lambda_v$ can therefore be recovered by requiring the mass and the infall velocity to be zero at $\lambda = 0$. Typically, we find that the value of $\lambda_v$ is close to the location of the first dark matter shell-crossing, which is obtained when dynamical relaxation is neglected.

The asymptotic analysis of equations (9-12) reveals the existence of two different types of solutions. For $-3 < n < -2$ ($\epsilon < 1/6$) the matter energy density is finite everywhere and close to the center the density slope goes to $\delta = -3(n+7)/(n+17)$, then spanning the range between $-6/7 \approx -0.86$ and $-1$. Since completely isotropic velocities, which we assumed at the center, require $\delta < -1$, it is unclear whether $\delta > -1$ can actually be obtained. However, the convergence of $\delta$ to its asymptotic limit at the center is rather slow (at $\lambda = 0.01r_{vir}$ the slope is still $\sim -1.3$ and $-1.2$ for $n = -2$ and $-2.5$, respectively, $\delta + 3(n+7)/(n+17) \approx 1/\log r$). Thus, except for extremely small values of $r$, our solutions should remain valid.

For $n > -2$ the matter energy density goes to infinity at the center and the density slope goes to $-3(n+9)/(n+5)$. However, since $n > -2$ is obtained only on scales, whose evolution is still in the linear regime, these solutions do not apply to any existing halos.

4. SELF-SIMILAR SOLUTIONS VS N-BODY CODES

We find that for $0.01 \lesssim r/r_{vir} \lesssim 1$ our solutions can be well approximated by the NFW fit (Figures 11 and 12). The discrepancy of order 10% in the circular velocity profile, which is seen at the outer part, where “shock” takes place, is quite expected, given our simplistic modeling of this transitional region. Closer to the center ($0.0001 \lesssim r/r_{vir} \lesssim 0.01$), our solutions predict steeper density slope than the NFW fit (though not as steep as predicted by Moore et al. (1999)). This is 1 Accidentally, when the dynamical relaxation process is neglected, the same slope is also obtained for $n > 1$. 1
and the values of $\alpha$ that produce the best fits to our solutions in the range $0.001 < r/r_{-2} < 1$ (0.16, 0.21 and 0.22, respectively, for $n = -2.5$ and $n = -2.75$) are close to $\alpha = 0.17$ found by Navarro et al. (2004). However, at $r \lesssim 0.001 r_{-2}$ (which has not been resolved by the N-body codes) the agreement between the equation (17) and our results breaks down.

5. SUMMARY

We have shown that the results of high-resolution N-body simulations of dark matter infall can be quite accurately reproduced by a simple self-similar accretion model. Moreover, the self-similar accretion model, being unlimited by computational constraints, may have an advantage over the N-body codes in reconstructing the density profile in the central region of dark matter halos. Naturally, it should be kept in mind that close to the center of a halo, a stellar disk or a supermassive black hole may strongly affect the density profile, making inadequate any model or code that rely exclusively on the dark matter gravity.

It is interesting to note that the two threshold values of $n$, which separate different types of self-similar solutions, have a special significance in the real Universe. Thus $n = -2$, which separates the solutions with finite and infinite central energy density, is also the largest possible value of $n$ on scales of existing virialized halos. The $n = 1$ threshold, which separates the solutions with finite and infinite gravitational potential in the center, seems also to be the largest value of $n$ on all scales (Spergel et al. 2004).
