Localized Translation of gurken/TGF-α mRNA during Axis Specification Is Controlled by Access to Orb/CPEB on Processing Bodies

Highlights

- gurken mRNA is not silenced by known repressors during its transport
- In nurse cells, gurken mRNA is not associated with processing bodies
- In nurse cells, lack of sufficient Orb/CPEB silences gurken mRNA translation
- In oocytes, gurken mRNA is associated with Orb on processing bodies and translated

In Brief

Localized transcripts that determine polarity are thought to be silenced during their transport by binding to translational repressors. Davidson et al. show that gurken mRNA, which sets up the primary Drosophila body axes, is instead regulated through lack of a translational activator, Orb, during its transport.
Localized Translation of *gurken/TGF-α* mRNA during Axis Specification Is Controlled by Access to Orb/CPEB on Processing Bodies

**SUMMARY**

In *Drosophila* oocytes, *gurken/TGF-α* mRNA is essential for establishing the future embryonic axes. *gurken* remains translationally silent during transport from its point of synthesis in nurse cells to its final destination in the oocyte, where it associates with the edge of processing bodies. Here we show that, in nurse cells, *gurken* is kept translationally silent by the lack of sufficient Orb/CPEB, its translational activator. Processing bodies in nurse cells have a similar protein complement and ultrastructure to those in the oocyte, but they markedly less Orb and do not associate with *gurken* mRNA. Ectopic expression of Orb in nurse cells at levels similar to the wild-type oocyte dorso-anterior corner at mid-oogenesis is sufficient to cause *gurken* mRNA to associate with processing bodies and translate prematurely. We propose that controlling the spatial distribution of translational activators is a fundamental mechanism for regulating localized translation.

**INTRODUCTION**

The regulation of translation in space and time is essential for a variety of physiological and developmental processes, such as axis specification in *Drosophila* and *Xenopus*, cell migration in fibroblasts, and synaptic plasticity in mammalian neurons (Medioni et al., 2012). Capped and polyadenylated mRNAs are by default translationally competent upon their export from the nucleus into the cytoplasm (Jackson et al., 2010). However, many mechanisms exist that can alter this default state and silence mRNA translation. Mechanisms include the binding to bona fide repressors (Richter and Lasko, 2011), denying access to ribosomes by inclusion in dense ribonucleoprotein (RNP) bodies (Weil et al., 2012), and preventing access to elf4E by elf4E binding proteins (Cao and Richter, 2002; Kamenska et al., 2014; Mintosh et al., 2007; Nakamura et al., 2004; Richter and Sonenberg, 2005; Stebbins-Boaz et al., 1999; Wilhelm et al., 2003) and by having a reduced poly(A) tail length (Gamberi et al., 2002; Igreja and Izaurralde, 2011; Ivshina et al., 2014). Such translational control can be coupled to mRNA localization so that transcripts are translationally repressed while being transported and only activated when they reach their final destination. In this way, protein function can be targeted to specific subcellular locations with high fidelity.

In the *Drosophila* oocyte, the primary body axes are established through mRNA localization coupled to temporal and spatial regulation of the translation of *oskar* (*osk*), *bicoid* (*bcd*), *nanos* (*nos*), and *gurken* (*grk*) mRNA (Weil, 2014). All of these mRNAs are transcribed in the nuclei of the adjoining nurse cells before being deposited in the oocyte and localized. During their transport through the nurse cells and within the oocyte, such transcripts are thought to be maintained in a translationally silent state through a number of mechanisms, including those described above, followed by de-repression or activation at their final destination (Besse and Ephrussi, 2008; Richter and Lasko, 2011). However, it is not known whether the mechanisms of repression of each transcript are the same; nor is it clear how many mechanisms of repression are at play in each case.

Translational regulation of *osk* mRNA, which specifies the posterior of the future embryo and initiates the formation of the posterior germline, has formed the paradigm in the egg chamber for translational control through the binding of specific repressors. During the transport of *osk* mRNA, Bruno (Bru/Arrest (Aret) binds to Bruno response elements (BREs) in its 3′ UTR. Together with polypyrimidine tract-binding protein (PTB), Bruno binding induces oligomerization of osk into translationally silenced particles that contain of up to 250 osk transcripts in the stage 10b oocyte (Besse et al., 2009; Chekulaeva et al., 2008; Kim-Ha et al., 1995; Little et al., 2015). BREs have been shown to act on osk mRNA in *trans*. Therefore, osk transcripts can confer Bruno-mediated repression to neighboring osk mRNAs within the same RNP (Hachet and Ephrussi, 2004; Reveal et al., 2010). This association breaks down when osk mRNA arrives at the oocyte posterior pole (Chekulaeva et al., 2006), allowing its translation. Furthermore, osk is subject to an
an additional parallel mode of translational repression through the action of Cup, the Drosophila homolog of the mammalian eukaryotic initiation factor eIF4E binding protein 4E-transporter (4E-T) and functional homolog of Xenopus Maskin (Cao and Richter, 2002; Kamenska et al., 2014; Minshall et al., 2007; Nakamura et al., 2004; Nelson et al., 2004; Richter and Sonenberg, 2005; Stebbins-Boaz et al., 1999).

Cup represses osk mRNA in association with eIF4E and Bru by inhibiting recruitment of the small ribosomal subunit to the 5' cap (Chekulaeva et al., 2006; Nakamura et al., 2004; Wilhelm et al., 2003). Moreover, Cup/Maskin/4E-T binds eIF4E and prevents it from associating with the translation initiation machinery (Cao and Richter, 2002; Kamenska et al., 2014; Minshall et al., 2007; Richter and Sonenberg, 2005; Stebbins-Boaz et al., 1999). Cup also works through repression of o018 RNA binding protein (Orb), the Drosophila homolog of cytoplasmic polyadenylation element binding protein (CPEB) (Latz et al., 1992; Wong and Schedl, 2011). Orb is required for the translational activation of osk mRNA by elongating its poly(A) tail (Chang et al., 1999; Castagnetti and Ephrussi, 2003; Juge et al., 2002), and high levels of Orb protein expression in the oocyte are ensured by the translational activation of orb mRNA by Orb protein (Tan et al., 2001). This feedback loop is controlled by the negative action of Cup, Ypsilon Schachtel (YPS), and Drosophila fragile X mental retardation (dFMR1) on orb translation (Costa et al., 2005; Mansfield et al., 2002; Wong and Schedl, 2011).

bcd mRNA is thought to be silenced in a similar manner as osk, but it utilizes a different translational repressor, Pumilio (Pum), which binds to conserved Nanos response elements (NREs) in the bcd 3' UTR (Gamberi et al., 2002). Similarly, Giorund (Kalifa et al., 2006) and Smaug (Nelson et al., 2004; Zaessinger et al., 2006) bind to a translational control element (TCE) in the 3' UTR of unlocalized nos mRNA to repress its translation (Cruces et al., 2000). During mid-oogenesis, our previous work has shown that localized bcd is translationally repressed in the core of processing bodies (P bodies), which consist of RNP complexes that are thought to regulate transcript stability and translation in a variety of systems (Decker and Parker, 2012; Weil et al., 2012). In the Drosophila oocyte, P bodies lack ribosomes and contain translational repressors, including the DEAD-box helicase maternal expression at 31B (Me31B) and Bru (Delanoue et al., 2007; Weil et al., 2012).

In contrast, there is less consensus regarding the mechanisms that are required for translational control of grk mRNA, particularly repression in nurse cells. Early in oogenesis, grk mRNA is localized and translated at the posterior of the oocyte, followed by a second phase of localization and localized expression at the dorso-anterior (DA) corner from mid-oogenesis. grk encodes a transforming growth factor-α (TGF-α) like signal that is secreted to the surrounding follicle cells to pattern dorsal cell fates (Neuman-Silberberg and Schüpbach, 1993). Dorso-ventral patterning also requires the heterogeneous nuclear RNP (hnRNP) Squid (Sqd), which has been shown to be necessary for correct Grk protein expression in the oocyte (Cáceres and Nelson, 2009; Clouse et al., 2008; Kelley, 1993; Li et al., 2014; Norvell et al., 1999). Although grk mRNA has been shown by biochemical analysis on ovaries (Norvell et al., 1999) to complex with Bruno through BRE-like sequences in its 3' UTR, these match only weakly the BREs found in osk (Reveal et al., 2011). Furthermore, fluorescent expression reporters containing the BRE-like sequences from the grk 3' UTR are subject to a low level of Bruno-mediated translational repression when compared with those containing osk BREs (Reveal et al., 2011).

We have previously established that, in the oocyte, grk mRNA is translationally repressed in transport particles and is then translated at its final destination in the DA corner of the oocyte, where it associates, in contrast to bcd, with the edge of P bodies (Weil et al., 2012). Importantly, the edge of P bodies has been shown to be decorated with ribosomes and enriched with Orb and Sqd (Clouse et al., 2008; Delanoue et al., 2007; Lantz et al., 1992; Li et al., 2014; Norvell et al., 1999; Weil et al., 2012). Interestingly, Orb has been shown to be required for the translation of grk, osk, and other localized mRNAs in the oocyte (Castagnetti and Ephrussi, 2003; Chang et al., 1999; 2001; Juge et al., 2002; Tan et al., 2001), and recently, Orb, together with Wispy (Wisp), a poly(A) polymerase, has been shown to be required for grk polyadenylation and Grk protein expression (Norvell et al., 2015). Indeed, phosphorylated, active Orb recruits Wispy and is required for the hyperadenylation and translation of grk (Norvell et al., 2015; Wong et al., 2011). However, it remains unclear when and where Orb acts in grk mRNA-localized expression in vivo and whether Orb association with P bodies is required to regulate grk translation.

Here, we address the mechanism in vivo by which translation of grk mRNA is prevented during its transport through nurse cells. We first tested the individual roles of previously suggested translational repressor proteins in the Drosophila egg chamber, including Me31B, Bru, and Sqd. We found that grk mRNA translational repression in nurse cells is not crucially dependent on any of these known repressors when tested individually, nor is grk present in the translationally silent core of P bodies in nurse cells. Instead, using immunofluorescence and electron microscopy, we found that wild-type nurse cell P bodies contain markedly lower levels of Orb compared with those in the oocyte. Increasing the levels of Orb protein within nurse cells by two independent methods causes grk mRNA to associate abnormally with nurse cell P bodies and also causes ectopic grk translation in nurse cells. Therefore, our data lead us to propose a model for spatial regulation of grk mRNA translation during Drosophila oogenesis in which grk transcripts are prevented from being translated in nurse cells by being denied access to sufficiently high levels of Orb, whereas, in the oocyte, grk is translated when it is anchored with Orb at the edge of P bodies.

RESULTS

grk Translational Silencing in Nurse Cells Is Not Dependent on Individual Translational Repressors as in osk Repression

Me31B and Bru are known to be crucial translational repressors of osk mRNA during its transport to the posterior of the oocyte because removal of each individually is sufficient to cause premature Osk protein expression (Chekulaeva et al., 2006; Nakamura et al., 2001, 2004; Wilhelm et al., 2003). We tested whether these regulators also individually repress grk mRNA translation during its transport. We first visualized the distribution of Grk...
protein in fly strains mutant for me31B using me31B heat shock-inducible germline clones (Nakamura et al., 2001). We found that, in me31B-null egg chambers, Grk protein is only expressed in the oocyte (Figure 1A), as in the wild-type. Similarly, Grk expression is unaffected in a number of allelic mutant combinations of aret (Bru mutant) (Yan and Macdonald, 2004; Figures 1B and 1B’; Figure S1). We also tested the role of Sqd, a heterogeneous nuclear RNA-binding protein, known to be required for grk mRNA anchoring (Delanoue et al., 2007) and translational repression in the oocyte (Cáceres and Nilson, 2009; Clouse et al., 2008; Li et al., 2014; Norvell et al., 1999). In sqd1 mutant oocytes, Grk protein is ectopically expressed along the entire anterior margin, resulting in a dorsalized egg (Figure 1C versus Figure 1C’)(Kelley, 1993; Norvell et al., 1999). However, we found that Grk protein is not expressed in nurse cells of sqd1 mutant egg chambers, showing that Sqd is not required for repressing grk translation in nurse cells (Figure 1C’). Collectively, we conclude that, unlike osk, none of the factors we tested...
Figure 2. grk mRNA Is Not Associated with P Bodies in Nurse Cells

(legend continued on next page)
individually repress grk mRNA translation during its transport in nurse cells.

Ectopically expressing osk mRNA leads to ectopic Osk protein expression in nurse cells, suggesting that the osk repression machinery is saturated by an excess of osk mRNA (Snee and MacDonald, 2004). To test whether a similar saturable mechanism exists to repress grk mRNA translation, we ectopically expressed grk mRNA to saturate any putative repression machinery. We used the UAS-Gal4 system to overexpress full-length grk transcripts (Bökel et al., 2006; Weil et al., 2012) at an average of 3-fold the level in wild-type nurse cells (Figure S2). This results in ectopic Grk expression, but only along the anterior margin of the oocyte, not in nurse cells (Figure 1D versus Figure 1D’). These data strengthen the notion that, in contrast to osk, grk translation in nurse cells is not mediated through the saturable binding of repressors.

**grk mRNA Associates Differently with P Bodies in Nurse Cells and Oocytes**

We next tested whether grk is maintained in a translationally silent state in nurse cells by localization to the ribosome-depleted and translationally silent core of P bodies in a similar manner to bcd in the oocyte (Weil et al., 2012). We visualized grk mRNA in nurse cells with single-molecule fluorescence in situ hybridization (smFISH) (Little et al., 2015) of egg chambers expressing Me31B::GFP, a canonical marker for P bodies in the oocyte (Weil et al., 2012). We found that small foci of grk mRNA, similar but weaker in intensity than oocyte transport particles (Figure 2A and 2A’), are evenly distributed in the nurse cell cytoplasm, with only a minority associated with the edge of nurse cell P bodies (Figures 2A and 2A’).

To test whether grk associates with P bodies in nurse cells at mid-oogenesis, we co-visualized grk in live nurse cells with the MS2-MCP system (grk-mCherry) (Bertrand et al., 1998; Forrest and Gavis, 2003; Jaramillo et al., 2008) and a number of proteins labeled by fluorescent protein traps (Buszczak et al., 2007). We found that grk-mCherry particles do not move with Me31B in nurse cells and transiently associate with P bodies at a significantly lower frequency (8%; n = 486) than in the oocyte (41%) (Weil et al., 2012; Figures 2B–2B’). These data suggest that, within our detection limits, grk mRNA does not move with P body proteins and is not localized to the interior of P bodies. We also tested whether the same was true at early stages by assessing the distribution of grk mRNA, Grk protein in fixed material (Figures 2C and 2D), and the interaction of grk mRNA with P bodies in live material (Figures 2F–2F’). We found that, in early stages, before the oocyte nucleus migrates, grk mRNA particles are dynamic all over the egg chamber, except when they are associated with P bodies at the posterior of the oocyte (Figure 2F’), where Orb is enriched (Figure 2E). We also found that Grk protein was enriched at the posterior of the oocyte and present at lower levels in other parts of the oocyte in a gradient that is consistent with diffusion away from its site of translation at the posterior (Figure 2D). Considering all of our data, we conclude that grk mRNA is likely to be translated at its site of anchoring in both early and late stages of grk mRNA localization. Moreover, grk mRNA is unlikely to be repressed by association with known saturable translational repressors either in the nurse cell cytoplasm or within P bodies.

**The Translational Activator Orb Is Largely Depleted in Nurse Cells**

Although we cannot completely eliminate the possibility that grk translation is controlled by a redundant and/or yet to be identified repression mechanism, our data prompted us to examine known translation activators such as Orb. To address this, we first re-characterized orb\textsuperscript{mel} mutants that expresses a truncated version of orb mRNA, resulting in lower levels of Orb protein from stage 7 of oogenesis onward (Christerson and McKearin, 1994). We observed a loss of Grk expression in orb\textsuperscript{mel} mutants (Figure S3), in agreement with previously published data (Chang et al., 2001). To begin to understand why grk mRNA is translated in wild-type oocytes but not in the nurse cells, we characterized the distribution of Orb protein in P bodies in the two compartments using immuno-electron microscopy (iEM) on ultrathin frozen sections of Drosophila egg chambers (Figure 3; Figure S4). We found that the level of Orb protein in nurse cell P bodies is 18 times lower than in oocyte P bodies (n = 10 P bodies; Figure 3D versus Figure 3D’). Using immuno-fluorescence detection on fixed egg chambers, we confirmed that the overall level of Orb is much lower in nurse cells compared with oocytes (Figures 3E, 4A, and 4C).

We then tested whether the overall composition of the nurse cell P bodies was different from those in the oocytes. We found that the key P body markers Me31B (Figure 3A) and Bru (Figure 3B) have a similar enrichment in nurse cells and the oocyte and that ribosomes are excluded from the nurse cell P bodies as they are from P bodies in the oocyte (Figure 3C). We also visualized P body protein composition by immunofluorescence and found that Me31B co-localizes with the canonical P body components Trailer hitch (Tral), Growl, eIF4E, Cup, and YPS in P bodies in nurse cells as they do in the oocyte (Figure S5). We conclude that the difference in Orb protein content of the P bodies in the two tissues is specific and that Orb is relatively depleted from nurse cell P bodies compared with those in the oocyte.

**Orb Is a Key Determinant for grk Translation in Nurse Cells**

To test whether low abundance of Orb in nurse cells is the key factor that prevents grk mRNA translation, we used the UAS-Gal4 system to drive the level of Orb in nurse cells to a similar level as in the wild-type oocyte (UASp-orb and TubulinGal4VP16) (Li et al., 2014). This approach also results in

Scale bars, 2 μm (A and B) and 10 μm (C and F).
a higher level of Orb protein in the oocyte of these egg chambers (Figure 4A versus Figure 4A'). Importantly, in these egg chambers, Grk protein is ectopically expressed in nurse cells in a highly reproducible pattern along nurse cell boundaries (Figure 4B versus Figure 4B'), as expected for a secreted protein that is normally trafficked into the overlying follicle cells when expressed at the DA corner (Queenan et al., 1999). We conclude that the ectopic expression of Orb in nurse cells drives the premature translation of grk mRNA in nurse cells. We propose that the absence of grk translation in wild-type nurse cells is due to the low level of Orb in this tissue.

Previous work has shown that orb transcripts can be detected in nurse cells as well as in the oocyte (Wong and Schedl, 2011) but that orb translation is repressed by Cup in nurse cells (Wong and Schedl, 2011). To test whether Cup is required to suppress the translation of orb mRNA in nurse cells and thus prevent grk translation, we stained cup mutant egg chambers with antibodies against Grk. We used cup1355, in which a P element insertion into the untranslated exon 1 causes a reduction in the level of Cup protein expression (Karpen and Spradling, 1992). As expected, we found an upregulation of Orb in cup1355 mutant nurse cells (Figure 4C versus Figure 4C'; n = 238), and, strikingly, we found that Grk protein is expressed in nurse cells and enriched along cell-cell boundaries, as in UAS-orb egg chambers (Figure 4D versus Figure 4D'). Interestingly, we found that Grk protein expression is stronger in cup1355 than UAS-orb egg chambers. This is consistent with Cup partly repressing excess Orb in UAS-orb egg chambers, whereas, in cup1355, orb translation is fully derepressed because of the lack of Cup. These results show that, when Cup-mediated repression of orb mRNA is absent in egg chambers, Orb is upregulated in nurse cells and grk is translated.

**grk Is Translationally Activated by Ectopic Orb on the Edge of Nurse Cell P Bodies**

At the DA corner of the oocyte, and most likely also at the posterior earlier in oogenesis, grk is translated when it docks at the
Orb-enriched edge of P bodies (Figures 2, 3, 4A, and 4C; Weil et al., 2012). If the key functional difference between P bodies in the oocyte and nurse cells is their level of associated Orb, then one would expect to find Orb at the edge of the nurse cell P bodies when it is ectopically expressed there. To test this prediction, we first examined Orb and Me31B distribution in the nurse cells of UAS-orb egg chambers and found that they colocalize (Figure 5A). Similarly, we found that Orb co-localizes with Tral in the nurse cells of cup mutant egg chambers (Figure 5B). To test whether ectopic Orb is enriched at the edge of nurse cell P bodies as it is in the oocyte, we performed 3D structured illumination microscopy (3D-SIM) (Schermelleh et al., 2008) on the OMX microscope (Dobbie et al., 2011). 3D-SIM reveals Orb puncta present at the edge of the Me31B-labeled P bodies in nurse cells (Figures 5C–5C’). We conclude that ectopic Orb in nurse cells is enriched at the edge of P bodies as it is at the DA corner of the oocyte.

To test whether ectopically expressing Orb in nurse cells targets grk to the edge of P bodies, allowing its translation, we performed smFISH for grk. As mentioned above, we found that, in nurse cells of wild-type egg chambers, grk seldom colocalizes with P bodies (Figures 2A and 5D–5D’). Conversely, in egg chambers in which Orb is ectopically expressed in nurse cells, grk foci colocalize 3-fold more with P bodies compared with the wild-type (Figures 5E–5E’). We conclude that overexpressed ectopic Orb associates with P bodies anchoring grk transcripts to activate translation. Therefore, we propose that grk is not translated in the nurse cells of wild-type egg chambers because, unlike in the oocyte, Orb is not present in nurse cells at the edge of P bodies.

**DISCUSSION**

Our results show that the translational regulation of grk in nurse cells, where the transcript is synthesized, occurs by a different mechanism from that of osk and bcd mRNA in the oocyte. osk is primarily translationally regulated by binding to individually essential translational repressors (Nakamura et al., 2001, 2004; Chekulaeva et al., 2006), whereas bcd is translationally repressed through its inclusion in the ribosome-depleted interior of P bodies (Weil et al., 2012). In contrast, our results show that translational silencing of grk mRNA during its transport in nurse cells is not affected when the repressors affecting osk are individually removed and that it is not localized within P bodies while being transported and repressed. These observations highlight a
Figure 5. When Orb Is Upregulated, It Is Expressed at the Edge of Nurse Cell P Bodies, and grk Is Targeted to P Bodies in Nurse Cells

(legend continued on next page)
Orb expression only in nurse cells is unclear, but we nevertheless found that grk is prematurely translated in nurse cells of cup mutants. Based on our results above and previously published work (Wong and Schedl, 2011), we favor the simplest interpretation: that, in cup mutants, Orb expression is elevated sufficiently to allow grk translation. However, we cannot completely exclude the possibility that Cup could also be involved directly in repressing grk translation in nurse cells through Cup’s known role in excluding eIF4E in the case of other transcripts (Nakamura et al., 2004; Wilhelm et al., 2003). Whether Cup acts by influencing Orb alone or also acts directly on grk mRNA translation, Cup and Orb spatially regulate translation of grk mRNA in egg chambers. It is interesting to note that, in *Xenopus*, CPEB activation of the translation of mRNA in the oocyte is temporally rather than spatially regulated through the action of hormone signals (Sarkissian et al., 2004), leading to activation of translation at precisely orchestrated times by lengthening of poly(A) tails (Hake and Richter, 1994).

Consistent with the published literature and its canonical function, Orb most likely acts on grk through cytoplasmic polyadenylation by binding to a polyadenylation element at the 3′ end of grk mRNA near the polyadenylation hexanucleotide signal (AAUAAA) (Chang et al., 1999; Fox et al., 1989; Kim and Richter, 2006; Norvell et al., 2015; Tan et al., 2001). Such an activity for Orb protein was first established for its homolog in *Xenopus*, CPEB (Fox et al., 1989; Hake and Richter, 1994). Orb is also known to bind osk and k(10) mRNAs and control their translation by modulation of poly(A) tail length (Castagnetti and Ephrussi, 2003; Chang et al., 1999, 2001; Juge et al., 2002; Tan et al., 2001; Wong and Schedl, 2011). Although there is no direct evidence that Orb binds grk mRNA, recent work shows that Orb and Wispy cooperate to polyadenylate localized grk mRNA in egg chambers (Chang et al., 2001; Norvell et al., 2015). It is certainly possible to imagine alternative models for how Orb acts on grk, such as polyadenylating and promoting the translation of other translational activators of grk. However, in the absence of any further direct evidence for such alternative mechanisms, we favor the simpler interpretation that Orb acts directly on grk by polyadenylating it and activating its translation.

Considering all of our data in the context of previously published work, we propose the following model for translational regulation of grk mRNA. While being transported in the nurse cell cytoplasm, grk mRNA is not translated because it fails to associate with Orb at the edge of P bodies. Only when grk enters the oocyte and moves to the dorso-anterior corner, where Orb levels are highest, does it become associated with Orb on the edge of P bodies, causing its localized translational activation (Figure 6).

Previous work indicates that grk translation is restricted to the posterior in early oocytes and at the DA corner at mid-oogenesis (Chang et al., 2001; Neuman-Silberberg and Schüpbach, 1993, 1994). More recent work suggests that this restricted translation is due to localization of active,

**Figure 6. grk Is Translationally Silenced in Nurse Cells by Being Denied Access to Its Translational Activator, Orb**

A model of grk translational regulation by restricted spatial access to Orb. In the nurse cells of WT egg chambers, P bodies lack in Orb, grk mRNA does not dock with P bodies and is not translated. At the oocyte DA corner, Orb is enriched at the edge of P bodies where grk mRNA docks. grk is translated and then secreted to the follicle cells around the oocyte nucleus.

---

**D** In ORR egg chambers, grk particles in nurse cells (D’) rarely colocalize with P bodies (D”) in nurse cells (16% of particles, n = 297).

**E** In UAS-orb egg chambers, grk particles in nurse cells (E’) colocalize with P bodies (E) (53% of particles, n = 395) and seem to be docked at the P body edge (E”).

Scale bars, 2 μm (A, B, and D–E”) and 1 μm (C–C”).
phosphorylated Orb (Norvell et al., 2015; Wong and Schedel, 2011). This may provide a plausible explanation for why grk mRNA does not associate with P bodies containing Orb in the middle of the oocyte; namely, if Orb is only phosphorylated and active in the DA corner. However, we cannot exclude the possibility that other factors, such as PABP55B, Encore (Enc), and Sqd, could also be required in the oocyte for localized grk translation (Clouse et al., 2008; Hawkins et al., 1996, 1997; Van Buskirk et al., 2000). Certainly, Sqd protein has been shown to bind grk mRNA directly and to regulate its translation (Li et al., 2014; McDermott et al., 2012; Norvell et al., 1999), possibly through anchoring, because previous work has also shown that, in the absence of Sqd protein, grk mRNA fails to anchor at the oocyte DA corner and is ectopically translated along the anterior (Cáceres and Nilson, 2009; Delanoue et al., 2007; Jaramillo et al., 2008; Norvell et al., 1999). Our data show that Sqd does not repress grk mRNA translation in nurse cells, leading us to interpret the function of Sqd in repression of grk, identified by previous biochemical work (Li et al., 2014), as occurring in the oocyte and not in nurse cells.

The well studied localized mRNAs osk, bcd, grk, and nos each have distinct profiles of translational regulation in time and space. For example, osk and grk are transported in a repressed state and are translationally activated when they arrive at their final destinations in the oocyte (Ephrussi et al., 1991; Neuman-Silberberg and Schüpbach, 1993), whereas localized bcd remains repressed within P bodies until egg activation (Weil et al., 2012). Our results suggest that spatial regulation of translation can be achieved by restricting the levels of a single activator, Orb. We propose that this could be a widespread mechanism of preventing translation of localized transcripts while they are being transported to their final destination.

EXPERIMENTAL PROCEDURES

Fly Strains

Stocks were raised on standard cornmeal-agar medium at 25°C. The wild-type was Oregon R (OrR). Mutant lines were as follows: hsFLP/w; me31B FRT40A, hsFLP/w; me31B FRT40A (Nakamura et al., 2001); aret was the gift from A. Nakamura, 1:1000; Bruno was the gift from J. Van Minnen, 1:300) (a gift from A. Nakamura, 1:1000), Bruno (a gift from A. Ephrussi, 1:300), and s ribo-490 (a gift from J. Van Minnen, 1:300).

Fluorescence Imaging

Flies were prepared and ovaries dissected and mounted for imaging according to standard protocols (Delanoue et al., 2007; Parton et al., 2011; Weil et al., 2012). Unless otherwise stated, the egg chambers shown in the figures were mid-oogenesis (stages 7–9). Imaging was performed on a DeltaVision CORE wide-field deconvolution system (Applied Precision, a subsidiary of GE Healthcare) based on an Olympus IX71 microscope using ×20 0.75 numerical aperture (NA) dry, ×100 1.4 NA oil, and ×100 1.3 NA silicon oil objectives, a 16-bit Roper Cascade II camera, and standard Chroma filter sets. Where required, images were deconvoluted with the SoftWoRx Resolve 3D constrained iterative deconvolution algorithm (Applied Precision). For live-cell imaging, grk mRNA particles were imaged close to the nurse cell nuclei at a single shallow plane of focus. Exposures of 300 ms at 3 frames/second were taken to achieve the optimum balance between signal-to-noise and temporal resolution for deconvolution and particle tracking. Analysis of fluorescence intensity in Orb antibody-stained egg chambers was performed using Fiji (V1.0, http://fiji.sc/wiki/index.php/Fiji). 3D-SIM imaging was performed on the OMX V3 microscope (GE Healthcare) as described previously (Weil et al., 2012).

Immunofluorescence on Fixed Drosophila Oocytes

Adult females flies were fattened as described above. An optimized fixation and staining protocol was then used to reduce possible antibody penetration artifacts that can be associated with immunofluorescence. Flies were dissected directly into freshly made 4% paraformaldehyde in PBS (0.1%) (paraformaldehyde stock solution: 16% methanol-free, ultrapure EM grade, Polysciences). Ovarioles were splayed using tweezers and a probe (Fine Science Tools) but not fully separated. Individual ovarioles were transferred into an Eppendorf tube and then 800 μl heptane was added before mixing briefly by vortex. Ovaries were fixed for no more than 15 min in total, followed by three rinses and three washes of 10 min in PBST. Following PBST washes, ovaries were washed for 5 min in PBS with Triton X-100 (PBXT, 0.01%) and then rinsed in PBST. Ovaries were blocked in 4% BSA in PBST for 30 min. Primary antibody was added at the required concentration in PBST for 2 hr at room temperature, followed by three rinses and three washes of 20 min in PBST. Secondary antibody was added at 1:500 in PBST for 1 hr at room temperature, followed by three rinses and three washes of 20 min in PBST. Ovaries were mounted on a glass slide in Prolong Gold antifade reagent (Life Technologies), and ovarioles were separated fully during mounting.

Single-Molecule FISH

Single-molecule FISH was performed using Stellaris (Biosearch Technologies) oligonucleotide probes 20 nt in length complementary to the grk transcript (CG17610, 48 probes), conjugated to CAL Fluor Red 590. Fixed ovaries were washed for 10 min in 50% PBST, 50% Hybe– solution (10% deionized formamide, 2x SSC, 2 mM ribonucleoside vanadyl complex, and 0.02 BSA) and then 10 min in Hybe– solution before pre-hybridization for 1 hr in Hybe+ solution (10% deionized formamide, 2x SSC, 2 mM ribonucleoside vanadyl complex, 0.02% BSA, and 10% dextran sulfate). Hybridization of probes was performed for 16–24 hr at a concentration of 25 nM in Hybe+ solution at 37°C. Ovaries were washed twice for 1 hr in wash buffer (15% deionized formamide and 2x SSC) and mounted in Prolong Gold for imaging.

SUPPLEMENTAL INFORMATION

Supplemental Information includes five figures and can be found with this article online at http://dx.doi.org/10.1016/j.celrep.2016.02.038.

AUTHOR CONTRIBUTIONS

A.D., R.M.P., C.R., T.T.W., and I.D. provided the intellectual basis of the work, designed the experiments, and wrote and edited the manuscript. A.D., R.M.P., and T.T.W. performed the experiments. R.M.P. and C.R. provided technical expertise for imaging and data analysis.
ACKNOWLEDGMENTS

We are grateful to Bram Herpers (Leiden) for the egg chamber IEM sections; A. Ephrussi (EMBL), A. Nakamura (RIKEN, Japan), P. Macdonald (University of Texas at Austin), M. Buszczak (University of Texas Southwestern Medical Center), T. Schupbach (Princeton University) and J. van Minne (University of Calgary) for fly stocks, antibodies, and reagents; the Bloomington Stock Center (Indiana University) for fly stocks; FlyBase for database information; P. Schedl (Princeton University) and T. Schupbach (Princeton University) for experimental advice; L. Schermelleh (Department of Biochemistry, University of Oxford) and Micron Oxford for help and advice with 3D-SIM; James Halstead (Friedrich Miescher Institute for Biomedical Research), Tatjana Trcek (NYC School of Medicine), and Lu Yang (Department of Biochemistry, University of Oxford) for assistance in optimization of protocols; and David Ish-Horowicz for critical reading of the manuscript. This work was supported by a studentship from the Wellcome Trust (grant 097304 to A.D.), Wellcome Trust Strategic Awards 091911 and 107457 supporting research at M.R.P., the University of Cambridge, ISSF (grant 097814 to T.T.W), and Wellcome Trust Strategic Awards 091911 and 107457 supporting advanced microscopy at Micron Oxford (http://micronoxford.com).
