Considering ground state of a quantum spin model as the initial state of the quantum battery, we show that both ordered and disordered interaction strengths play a crucial role to increase the extraction of power from it. In particular, we demonstrate that exchange interactions in the xy-plane and in the z-direction, leading to the XYZ spin chain, along with local charging field in the z-direction substantially enhance the efficiency of the battery compared to the model without interactions. Moreover, such an advantage in power obtained due to interactions is almost independent of the system size. We find that the behavior of the power, although measured during dynamics, can faithfully mimic the equilibrium quantum phase transitions present in the model. We observe that with the proper tuning of system parameters, initial state prepared at finite temperature can generate higher power in the battery than that obtained with zero-temperature. Finally, we report that defects or impurities, instead of reducing the performance, can create a larger amount of quenched averaged power in the battery in comparison with the situation when the initial state is produced from the spin chain without disorder, thereby showing the disorder-induced order in dynamics.

I. INTRODUCTION

In modern era, devices which store energy for later purposes are extremely useful to fulfill our daily needs ranging from communication appliances to medical accessories like artificial cardiac pacemakers, hearing aids. Prominent examples of such energy storage include batteries consisting of one or more chemical or electrochemical cells, converting chemical energy to electrical one. They can either be disposable or rechargeable – the later ones can be charged externally by using electricity and are very convenient due to their multiple usage facilities. On the other hand, it has been realized over a last few decades that technologies like computers, communication gadgets based on quantum mechanical principles can perform more efficiently than their classical analogs [1]. Importantly, such devices have already been built in laboratories by using physical systems like photons, ion-traps, superconducting qubits [2–5].

It is therefore natural to ask whether quantum mechanical properties like coherence [6], entanglement [7] can also play a role to efficiently store or generate energy. In this respect, two distinctly different versions of quantum batteries are proposed – (1) arbitrary number of independent quantum systems acts as cells of a battery and entangling unitary or nonunitary operations are applied for a suitable time period to drive the system leading to the extraction of energy from it [8–10]; (2) secondly, the ground state of an interacting spin model can be considered as the initial state of the battery which can then be used as a storage media where charging is performed via quantum mechanically allowed operations [11]. Although the former proposal have extensively been studied in recent years, the later one have recently been explored and was shown that nature of coupling of the initial ordered Hamiltonian is crucial for obtaining the improvement in the power [10]. In this paper, we concentrate on the second kind where the initial state of the battery is prepared in the ground or thermal state of the quantum spin chain and local charging field is used to drive the system required to extract power from the battery. With the development of ultracold atoms trapped in optical lattices or in trapped ions or in polar molecules, the basic ingredient for quantum battery, quantum many-body Hamiltonians, can currently be implemented and engineered in laboratories, thereby creating possibilities of manufacturing quantum technologies using these systems [3, 4, 12, 13].

On the other hand, the systems without any impurities or defects are in general difficult to build and at the same time, keeping them at absolute zero temperature is also hard. Therefore, disordered systems [14, 15] and effects of temperature on physical properties of many-body systems have attracted lots of attention in recent times [16, 17]. Moreover, it was discovered that the disordered models posses exotic phases like Bose glass [18] (cf. [19, 20]) which are not present in the homogeneous systems as well as show counter-intuitive phenomena like Anderson localization [14], many-body localization [21], high-$T_c$ superconductivity [22]. These disordered systems can also be created in a controlled manner in ultracold gases, and hence one can observe these phenomena and quantum phases in experiments, making this field more appealing [23].

In this paper, we first investigate the role of many-body interactions, ordered as well as disordered, of the parent Hamiltonian and the temperature of the initial state on the efficiency of the battery. Specifically, we show that in case of the transverse $XY$ and the $XYZ$ model without disorder, power of the battery critically depends on the interactions and its characteristics like the ferromagnetic or the antiferromagnetic ones. We also find that the advantages in power generation due to the interactions remain almost same for different system sizes. Moreover, signatures of quantum critical points, present in these models, are clearly visible in the trends of the power. Note that although the output power of the battery is measured in the evolution of the system, it can still indicate the equilibrium property of the parent Hamiltonian (cf. [24]). We also show that suitable tuning of interactions and temperature lead to a situation where power of the quantum battery increases with the increase of tempera-
perature, although one intuitively expects that the initial state prepared at high temperature can destroy the effectiveness of the quantum battery. Moreover, we observe that the Gaussian-distributed random interaction strengths, both in the \(xy\)-plane and in the \(z\)-direction of the \(XYZ\) model, enhance the quenched-averaged power compared to that of the ordered case. Such counter-intuitive phenomena were already demonstrated in physical quantities like magnetization, correlation length, entanglement computed in the static scenario i.e., in the ground or in the thermal states of the disordered models [25, 26]. Our results indicate that such advantages can also be found in closed dynamics of the systems with defects.

The paper is organized as follows: In Sec. II, we introduce the concept of quantum battery and the respective measure to quantify its efficiency. We then discuss the quantum spin models, both ordered and disordered ones, that we use for modelling quantum battery (Sec. III). We then present the results in Sec. IV for ordered spin models with the initial states of the battery being either the ground state or the thermal state with finite temperature. Finally, we show that models with random exchange interactions can increase the quenched averaged power of the battery in Sec. V. The conclusion is in Sec. VI.

II. QUANTUM BATTERY BUILT FROM QUANTUM SPIN CHAIN: SET THE STAGE

A quantum battery is usually considered as \(N\) identical and independent quantum mechanical systems, in arbitrary dimension, expressed by a Hamiltonian, \(H_0\), having non-degenerate eigenvalues. To extract work, the system is driven by an interacting Hamiltonian, acting on the total \(N\)-party system, \(H_{\text{charging}}\), which can, in general, be time-dependent [8–10]. Such Hamiltonian can, in principle, create entanglement in the dynamical state.

In contrast to this, we choose a quantum battery, made up of \(N\) interacting spin-1/2 particles governed by a Hamiltonian, \(H_0\). In this work, one of our primary goal is to study the effect of interactions and its nature on the efficiency of the battery. Hence the Hamiltonian considered here constitutes of two parts, given by

\[
H_0 = H_{\text{field}} + H_{\text{int}},
\]

where \(H_{\text{field}}\) represents the external local magnetic field, while \(H_{\text{int}}\) is two or more-body interactions between the spins of the spin-chain. To drive the system (or more precisely, the battery), a local charging field \(H_{\text{charging}}\), is applied on each individual spin. See Fig. 1 for the schematic representation of the battery. With \(H_{\text{int}} = 0\), the battery and its charging process only consist of local terms, so that it becomes exactly analogous to a classical situation. Note that the similar scenario is considered in Ref. [11] although unlike the local field, the interacting part of the Hamiltonian along with the charging field is employed to extract the work from the battery.

Let us first notice that one can trivially increase the efficiency of the battery by multiplying some constant (greater than one) to \(H_0\), or by increasing the magnitude of the local part, \(H_{\text{field}},\) of the Hamiltonian. To make the analysis non-trivial, we normalize \(H_0\) as

\[
\frac{1}{E_{\text{max}} - E_{\text{min}}} \left[ 2H_0 - (E_{\text{max}} + E_{\text{min}}) \mathbb{I} \right] \rightarrow H_0
\]

where \(E_{\text{min}}\) and \(E_{\text{max}}\) are minimum and maximum energy eigenvalues of \(H_0\) respectively. Due to this normalization, the spectrum of \(H_0\) is now bounded in \([-1, 1]\) irrespective of the parameter values. This normalization enables us to exactly find out the consequence of \(H_{\text{int}}\) in power compared to the case with vanishing interaction part, i.e., \(H_{\text{int}} = 0\) which is the classical scenario.

The charging of the battery in a closed system takes place according to the unitary operator, given by

\[
U(t) = \exp(-iH_{\text{charging}}t),
\]

which is responsible for the time-evolution of the initial state, \(\rho(t = 0)\), of the battery. Initially, the battery is prepared either in (i) the ground state of the normalized Hamiltonian, which corresponds to the situation of absolute zero temperature, or in (ii) the canonical equilibrium state, \(\rho_{\text{eq}} = \exp(-\beta H_0)/Z\), for a given inverse temperature, \(\beta = 1/\kappa T\), with \(Z = \text{Tr}(\exp(-\beta H_0))\) and \(\kappa\) being the corresponding partition function and the Boltzmann constant respectively. It is important to note here that since the absolute zero temperature is hard to achieve in experiment, a state with finite temperature is a natural choice for the initial state of the battery. At a particular time instant \(t\), the total work-output by the battery can be defined as

\[
W(t) = \text{Tr}(H_0\rho(t)) - \text{Tr}(H_0\rho(t = 0)),
\]

where \(\rho(t) = U(t)\rho(t = 0)U(t)\dagger\) is the evolved state of the system. The corresponding average power for a given time \(t\) can be written as \(P(t) = \frac{W(t)}{t}\). The aim in preparing the battery is to maximize the extractable power, and hence it is important to choose a proper time when the evolution should be stopped. Towards this objective, the maximum average power obtained from a given battery can be quantified as

\[
P_{\text{max}} = \max_t \frac{W(t)}{t},
\]

where the maximization is performed over time, \(t\). In the rest of the paper, we call \(P_{\text{max}}\) as the power of the battery which is the maximum power, obtained in optimized time.
III. QUANTUM SPIN MODEL AS BATTERY

Let us describe the properties of quantum XYZ Heisenberg spin chain with magnetic field which we consider as $H_0$. Its ground or canonical equilibrium state serves as the possible initial state of the battery. The Hamiltonian consisting of $N$ spin-$1/2$ particles with open boundary condition reads as

$$
H_0 = \frac{1}{2} \hbar \sum_{j=1}^{N} \sigma_j^x + \frac{1}{4} \sum_{j=1}^{N-1} J_j [(1 + \gamma) \sigma_j^x \otimes \sigma_{j+1}^x + (1 - \gamma) \sigma_j^y \otimes \sigma_{j+1}^y] + \frac{1}{4} \sum_{j=1}^{N-1} \Delta_j \sigma_j^z \otimes \sigma_{j+1}^z, \tag{6}
$$

where $\sigma^\alpha (\alpha = x, y, z)$ represents the usual Pauli spin matrices, $\hbar$ is the strength of the external magnetic field at each site, $0 \leq \gamma \leq 1$ is the anisotropy constant, and $\{J_j\}, \{\Delta_j\}$ are the nearest neighbor coupling constants in the $xy$-plane and in the $z$-direction respectively. They may or may not depend on site $j$. In a closed system, the quantum battery can be charged by applying local external magnetic field in the $x$-direction with strength $\omega$, as

$$
H_{\text{charging}} = \frac{\omega}{2} \sum_{j=1}^{N} \sigma_j^x. \tag{7}
$$

To obtain the work and then power of the battery, the time-dynamics is computed by constructing the unitary operator via Eq. (7) where the ground or the thermal state of the spin model in Eq. (6) is used as the initial state. It is important to stress here that realizability of these models by currently available technologies create possibilities to implement the proposed battery in laboratories.

A. Quantum XYZ Heisenberg model with homogeneous interaction

Depending on the scenarios, whether the sets, $\{J_j\}$ or $\{\Delta_j\}$ is site-independent or not, the spin-system can be called ordered or disordered. In this paper, we will explore both the cases. Let us first consider the system with $J_j = J$ and $\Delta_j = \Delta$, i.e. the parameters involved in Eq. (6) are site independent, leading to the ordered spin chain. In one dimension, Eq. (6) represents a paradigmatic families of Hamiltonians with nearest neighbor interactions, having a rich phase diagram at zero temperature. Let us now discuss some important sub-classes of $H_0$, and their phase portraits.

1. $\Delta = 0$, and $\gamma \geq 0$ [27, 28]: $\gamma = 0$ represents the transverse $XX$ spin chain, while the $XY$ spin model having transverse magnetic field is with $\gamma \neq 0$. They belong to two different universality classes – the former one has a gapless spin-liquid (SL) phase for $|J/\hbar| > 1$, and a paramagnetic (PM) phase for $|J/\hbar| < 1$, while the later one belongs to the Ising universality class, consisting of a PM ($|J/\hbar| < 1$), an antiferromagnetic (AFM) ($J/|\hbar| > 1$), and a ferromagnetic (FM) ($J/|\hbar| < -1$) phases. Both the models can be solved analytically by Jordan-Wigner transformations [27, 28] for arbitrary system size including in the thermodynamic limit.

2. $\gamma = 0$, $\Delta \neq 0$ [29–31]: The model is known as the XXZ spin chain. For $h = 0$, the model is integrable – with $J = 1$, there is an AFM region for $\Delta > 1$, and $\Delta < -1$ corresponds to the ferromagnetic (FM) one, while $-1 < \Delta < 1$ is the gapless SL phase. By using different approximate and numerical techniques, quantum critical lines and their corresponding phases of the system with $h \neq 0$ has also been explored [29]. For example, with small values of magnetic field and $\Delta$, a new phase, Néel order in the $y$-direction, develops, which is known as spin-flop phase (SF).

3. $\Delta \neq 0, \gamma \geq 0$ (XYZ model)[32–34]: The model is not exactly solvable. Several numerical and approximate studies of the XYZ model with field reveal that it has a very rich phase diagram. In particular, like the XXZ model, it also possess FM, AFM and SF phases although for non-zero values of $\gamma$, two new quantum phase transitions [35] of different kinds appear – one from SF to a new phase called gapless floating phase (FP), while another one is from the FP to the AFM phase.

We will show in the next section that tuning parameters leading to different quantum spin models play an essential role to build and maintain the performance of the battery.

B. Quantum XYZ model with random interaction strength: Disordered quantum spin model

Let us now consider the system, in which one of the interaction strengths depends on sites. Such a system can be found in nature due to the presence of impurity in materials, and at the same time, it can also be created and controlled in laboratories with cold atoms in optical lattices, linear chains of ions etc. [23]. Moreover, we assume that disorder here is “quenched”, which means that the change of disorder in parameters under study
remains fixed for certain times, a much longer duration than that of the evolution of the system. In this paper, two situations are considered which are as follows:

1. The nearest neighbor exchange interaction in the $xy$-plane, $\{J_j/|h|\}$, are randomly chosen from a Gaussian distribution with mean $J/|h|$ and the standard deviation $\sigma_J$ which we refer as the strength of disorder. $\sigma_J = 0$ corresponds to the ordered case. Here, $\{\Delta_j/|h|\} = \Delta/|h|$ remains independent of the sites. Quenched averaging is performed by first computing the power of the battery for each realization with random-distributed $\{J_j/|h|\}$, and then by taking the average over all realizations. Mathematically, for a physical quantity, $O$, and for a randomly chosen parameter, $\{X_j\}$, with mean $\bar{X}$ and standard deviation $\sigma_X$ involved in the system, quenched averaged quantity can be represented as

$$
\langle O(\bar{X}, \sigma_X) \rangle = \int \ldots \int O(X_j) d\{X_j\},
$$

where the integration is carried out with respect to the probability distribution by which the $\{X_j\}$ are chosen. In our case, the power of the quantum battery ($P_{\text{max}}$) is the physical quantity, which has to be quenched averaged over the parameter-space, $\{J_j/|h|\}$, denoted by $\langle P_{\text{max}} \rangle$.

2. Fixing $\{J_j/|h|\} = J/|h|, \forall j$, we also study the effect of disorder on power by choosing $\{\Delta_j/|h|\}$ randomly from a Gaussian distribution with mean $\bar{\Delta}/|h|$ and standard deviation $\sigma_\Delta$.

IV. INTERACTION ENHANCES THE POWER: ORDERED CASE

In this section, we address the question whether nearest neighbor interactions can be beneficial for increasing the extraction of power from the battery. To demonstrate this, we first consider the ground state as the initial state of the quantum ordered $XY$ model with transverse magnetic field as the battery, and then move on to the role of interactions in the $z$-direction by considering the $XYZ$ model. We further study the effects of finite temperature on the efficiency.

A. Effects of interaction term in the $XY$ model

Let us consider the ground state of the transverse $XY$ model, and compute the power, $P_{\text{max}}$, with the variation of $J/|h|$ for fixed values of system size, $N$. The behavior of power, depicted in Fig. 2(a), shows that the battery prepared by using interacting Hamiltonian has higher power as output for certain system parameters than that of the system without interactions. For demonstration, we fix some values of $\gamma$, and the strength of the charging field as $\omega = 2|h|$. The interesting observations in the pattern of $P_{\text{max}}$ are listed below:

1. Positive vs. negative interaction strength. Positive and negative coupling constants, i.e., $J/|h| > 0$ and $J/|h| < 0$ indicate the nature of interaction to be antiferromagnetic and ferromagnetic ones. As depicted in Fig. 2(a), we observe that $P_{\text{max}}$ increases when $0 < J/|h| \lesssim 1$, and reaches its maximum value close to $J/|h| \approx 1$, while it decreases for $J/|h| < 0$. Typically, static physical quantities, like magnetization, classical correlators, entanglement [7], in the ground state are symmetric across $J/|h| = 0$-line [13, 36]. The asymmetry observed here arises due to the choice of uniform charging field in the $x$-direction, given in Eq. (7). However, the pattern of $P_{\text{max}}$ clearly establishes that the interaction of $H_0$ helps to improve the performance of the battery in the paramagnetic phase of the $XY$ model. Moreover, we find that the observation is independent of the anisotropy parameter, $0 < \gamma < 1$ (see observations 2. and 3.).

2. Dependence on $\gamma$. Maximal power of the battery greatly depends on the anisotropy parameter, $\gamma$ as it is evident from Fig. 2(a). Among all the $\gamma$ values, if the battery is initially in the ground state of the $XX$ model having $\gamma = 0$, the power output is maximum, as compared to the other values of $\gamma$. Also, from Fig. 2(a), we find that the range of $J/|h|$, where the advantage in power can be obtained, shrinks with increasing $\gamma$. To visualize the $\gamma$-dependence, we identify the interaction strength, $J/|h|$, for which $P_{\text{max}}$ reaches its maximum value,
which we refer as $J_{\text{max}}/|h|$. We then investigate the behavior of $J_{\text{max}}/|h|$ with $\gamma$ for different system sizes, as shown in Fig. 3(a).

3. Role of exchange interaction: Scale invariance.

The interaction part, $H_{\text{int}}$, in $H_0$ is important in $P_{\text{max}}$ as already discussed. To quantify its influence, we introduce a quantity,

$$P_{\text{adv}} = P_{\text{max}}(J_{\text{max}}/|h|) - P_{\text{max}}(J/|h| = 0), \quad (9)$$

where $P_{\text{max}}(J_{\text{max}}/|h|)$ and $P_{\text{max}}(J/|h| = 0)$ are respectively power measured at $J_{\text{max}}/|h|$ defined above and at $J/|h| = 0$. $P_{\text{adv}}$ reaches its maximum value at $\gamma = 0$, and decreases with the increase of $\gamma$ as seen in Fig. 3(b). Specifically, we find that when $\gamma = 0$, nonvanishing interaction, in the chain of $N = 8$ sites, can produce up to 28.8% increase in power, thereby showing the relevance of quantum battery. Note, however, that for $\gamma = 1$, we find that $P_{\text{adv}} = 0$, i.e., the local scenario is most efficient, and interaction does not help. Importantly, we observe that $P_{\text{adv}}$ does not depend on the number of spins in the chain, showing scale invariance property of the advantage.

4. Quantum phase transition signaled through power.

The second-order quantum phase transition [16, 37] in the XY model at zero temperature can be detected by the first derivatives of several physical quantities, which include correlation length [16], entanglement [7], quantum discord [38] etc. Since $P_{\text{max}}$ is measured in the evolution, it is not apriori clear that it can identify quantum phase transitions. We here show that for low values of $\gamma$, the dynamical quantity, $P_{\text{max}}$ itself, can signal quantum phase transition by showing a finite jump around $|J/|h| \approx 1$. For higher values of $\gamma$, $P_{\text{max}}$ changes its curvature from concave to convex so that its derivative shows the kink. It is interesting to note here that in a different context of dynamical phase transition [24], quantity like Loschmidt echo defined as the distance between the ground and the evolved states of the quantum spin model can also mimic the equilibrium phase transition.

5. Dependence of power on $N$.

With the variation of $N$, we observe that in the range of $-1 \lesssim J/|h| \lesssim 1$, the power does not change its behavior substantially. However, $J_{\text{max}}/|h|$ which leads to maximum $P_{\text{max}}$ shifts towards $J/|h| = 1$ with the increase of $N$, although the value of the maximum power, as well as maximum advantage in power remain almost unaltered with $N$ (see Figs. 3 and 4). This is possible because the curvature of $P_{\text{max}}$ becomes steeper with $N$. On the other hand, finite-size effects on $P_{\text{max}}$ are visible for $J/|h| < -1$ as well as for $J/|h| > 1$ (Figs. 2(a) and 4).

6. Scaling.

Since power of the battery can detect equilibrium quantum phase transition as discussed above, it is now natural to ask the scaling law followed by it. Ambitiously, we find the finite-size scaling of critical points, as indicated by the behavior of $P_{\text{max}}$ as

$$\left( \frac{J_N - J_0}{\hbar} \right) = 1.039 \times N^{-1.78}, \quad (10)$$

for both FM ↔ PM and AFM ↔ PM transitions for $\gamma = 0.1$ (Fig. 4 insets). Here $J_N/|h|$ is computed where the power shows a jump for a fixed value of $N$, while $J_0/|h| = 1$ as known for the transverse quantum XY model in the thermodynamic limit.

7. Role of entanglement.

Since we have already shown that many-body interactions can increase the efficiency of a quantum battery, it is now natural to ask whether inter-spin entanglement plays a role in the performance or not. To answer this query, we compute bipartite entanglement [7] of the reduced density matrix obtained by tracing out all the parties except two from the middle of the chain of both the initial state and the state at the time when $P_{\text{max}}$ is optimized. We find that entanglement can be a necessary ingredient to extract more power, but not sufficient, which is in parity with the earlier results (see [10] and references therein). This is because entanglement qualitatively mimics the features of $P_{\text{max}}$, as shown in Fig. 3(a), for $J/|h| > 0$ and for different values of $\gamma$ while it also symmetrically increases in the region, $-1 \lesssim J/|h| < 0$, where $P_{\text{max}}$ decreases.

B. Introduction of interaction in $z$-direction leads to enhancement in Power

Let us now move to the $XYZ$ model with magnetic field, given in Eq. (6). We will now address the question whether the additional interactions in the $z$-direction, i.e., the model with $\Delta/|h| \neq 0$ is required to increase the
power of the battery. As before, the battery is initially prepared as the ground state of this model.

Comparing Figs. 2 (b), (c), and (d) with (a), we find that with the increase of \( \Delta /|h| \), the power increases in the region of \( J/|h| < 0 \) where the power was decreasing in absence of \( \Delta /|h| \), thereby establishing the usefulness of the coupling in the \( z \)-direction. Moreover, we observe that for moderate values of \( \Delta /|h| \), there is a lower bound on the coupling constant in the \( xy \)-plane, denoted by \( J_c /|h| < 0 \), where \( P_{\text{max}} \) increases beyond the value obtained with the initial state of the battery being the ground state of the Hamiltonian without any \( XY \) exchange interaction, i.e., with \( J/|h| = 0 \). Note, however, that the model with \( J/|h| = 0 \) and \( \Delta /|h| \neq 0 \) does not correspond to the classical scenario, since the field, given to drive the system, is in the complementary direction of the exchange interaction of the parent Hamiltonian. Again, with the increase of \( \gamma \), \( J_c /|h| \) decreases although it is much bigger than that obtained for the \( XY \) model. It shows that even if the tuning of the system parameters cannot be performed properly, the \( XYZ \) model is more appropriate to build the quantum battery than the \( XY \) model.

\section*{C. Effect of temperature on Power of the battery}

We have already shown that the zero-temperature state as the initial state of an interacting Hamiltonian is advantageous for generating high amount of power in the quantum battery. We will now see whether such improvement persists (or even increases) when the initial state is the thermal state, \( p_{th} \), having a finite temperature. This is important because in the laboratory, absolute zero temperature is not easy to obtain. To produce power, local charging Hamiltonian, in Eq. (7), is again applied to each site. As one expects, we see that \( P_{\text{max}} \) vanishes for infinite temperature, i.e., for \( \beta = 0 \), then starts increasing as \( \beta \) increases, and finally saturates to the power of the zero-temperature. However, we notice that the variation of \( P_{\text{max}} \) with increasing \( \beta \) is not always monotonic, and can have one or more nonmonotonic bumps depending on the system parameter, which signify that we can have situations, where the battery performs more efficiently at higher temperature than the lower ones. More interestingly, and quite counter-intuitively, it turns out that battery may output more power at finite temperature than that of the absolute zero temperature.

Quantitatively, we define a quantity which can capture the advantages gained at finite temperature over the zero-temperature, given by

\[ P_{\text{max}}^{T-\text{adv}} = \max[0, P_{\text{max}}(T > 0) - P_{\text{max}}(T = 0)], \]

where \( P_{\text{max}}(T > 0) \) and \( P_{\text{max}}(T = 0) \) are the extractable power, obtained with the thermal state and with the ground state respectively. Indeed, we find that \( P_{\text{max}}^{T-\text{adv}} \) is positive for certain choices of \( J/|h| \) and \( \beta /|h| \) (see Fig. 5 for four sets of values of \( (\Delta /|h|, \gamma) \)). Numerical simulations also confirm that changing system parameters does not alter the results qualitatively.

\section*{V. DISORDER-ENHANCED POWER FROM THE BATTERY}

In this section, we examine how the presence of impurities in interactions can induce in power generation by the battery. The observations are mainly classified into two
FIG. 6: (Color online.) Quenched averaged power, $\langle P_{\text{max}} \rangle$, against $J/|h|$ for different disorder strength $\sigma_J$. Note that $\sigma_J = 0$ refers to the ordered case. Disorder is introduced in the coupling constant in the $xy$-plane, $J_j/|h|$, for fixed values of $\Delta/|h|$ and $\gamma$. The choices of $\Delta/|h|$ and $\gamma$ are same as in Fig. 5. The twin advantages mentioned in the text can be visualized from the plots with $\Delta/|h| \neq 0$. Both the axes are dimensionless.

A. Effects of Randomness in $XY$-exchange interaction

Let us concentrate on the first scenario with $\{\Delta_j/|h|\} = \Delta/|h|$ and the disorder being in $\{J_j/|h|\}$, chosen from the Gaussian distribution with a given mean, $\bar{J}/|h|$, and a standard deviation, $\sigma_J$. As mentioned in Sec. III B to obtain the quenched averaged value of the power, we here perform averaging over 5000 realizations, which we find to be sufficient to converge $\langle P_{\text{max}} \rangle$ up to a second decimal place. Below we emphasize our primary observations regarding the effects of randomness in $XY$-couplings as depicted in Fig. 6.

1. For $\Delta/|h| = 0$, i.e., for the transverse $XY$ model, increasing the mean interaction strength, $\bar{J}/|h|$, from $\bar{J}/|h| = 0$, does not help to increase the maximum power over the ordered scenario (Fig. 6 (a)-(b)). On the other hand, for given values of system parameters, there are situations, both in $\bar{J}/|h| > 0$ and $\bar{J}/|h| < 0$-regions, where increasing disorder strength, $\sigma_J$, results better production of power, $\langle P_{\text{max}} \rangle$, than that in the ordered case, thereby showing disorder-induced power output. Such advantages are prominent for lower values of the anisotropy parameter, $\gamma$, and negative values of $\bar{J}/|h|$ (Fig. 6 (a)-(b)).

2. Interestingly, in presence of strong and constant interaction in the $z$-direction (e.g., when $\Delta/|h| = 1$ as shown in Fig. 6 (c) and (d)), we find that for $\bar{J}/|h| < 0$, there are situations where we can get better quenched averaged power output by increasing $\bar{J}/|h|$ than the one obtained in the ordered $XYZ$ model. Secondly, for fixed values of system parameters, $\bar{J}/|h|$, battery produces more power with the increase of $\sigma_J$. Specifically, we observe that there exists regions in $\bar{J}/|h|$ where $\langle P_{\text{max}} \rangle$ with $\sigma_J = 1$ produces maximum power than any values of $\sigma_J$. Moreover, as shown in all the situations, increase in the anisotropy parameter suppresses the power generation from the battery.
B. Effects of Impurities in the interaction strength in $z$-direction

Let us now move to the case where randomness is introduced in the interaction strength in the $z$-direction, i.e., \([\Delta_j/|h|]\) are taken randomly from Gaussian distribution with mean, \(\overline{\Delta}/|h|\), and standard deviation, \(\sigma_{\Delta}\), with keeping \(\langle J_j/|h| \rangle = J/|h|\) fixed for every sites (Fig. 7). As before, we take 5000 different realizations for quenching.

Comparing Figs. 7 (a) - (b) with 6 (a) - (b), we safely claim that the pattern of \((P_{\text{max}})\) for model with \(\overline{\Delta}/|h| = 0\) is almost identical to the disordered transverse XY model. Note that \(\overline{\Delta}/|h| = 0\) refers to the disordered XYZ model and does not correspond to the XY model.

However, it turns out that the Hamiltonian with \(\overline{\Delta}/|h| > 0\) is much more beneficial (see Fig. 7) as compared to the previous cases, where randomness was in \(\{J_j/|h|\}\) and also when \(\overline{\Delta}/|h| = 0\). Two prominent differences between these two types of disordered scenarios are as follows:

1. Advantages in power with increasing disorder strength and fixed values of system parameters are less affected by increasing $\gamma$ than any previous situations considered in this paper. Instead of diminishing the power, we find that the moderate values of $\gamma$ leads to more efficiency in power production of the battery in presence of strong disorder.

2. With non-zero $\overline{\Delta}/|h|$, we observe that the quenched averaged power increases with the variation of $\sigma_{\Delta}$ for the entire region of $|J/|h|\$, thereby showing advantages of systems having impurities for preparing quantum battery. In particular, as seen in Fig. 7(d) with $\overline{\Delta}/|h| = 1$ and $\gamma = 0.4$, $\sigma_{\Delta} = 1$ generates maximum quenched power, $(P_{\text{max}})$ than any other values of $\sigma_{\Delta}$. Such phenomena can be referred as disorder-induced order observed in dynamics.

VI. CONCLUSION

Batteries convert chemical energy to the electrical one, thereby accomplishing our high demands of electricity in daily life. On the other hand, technological developments lead to the devices which is smaller and smaller in size, and hence the effects of quantum mechanics on them are inevitable. Moreover, it was discovered that quantum-based technologies are more efficient than the existing classical ones. Therefore, it is natural to explore whether storage devices can also be improved by using quantum mechanics. It was recently found that this is indeed the case.

If we build quantum battery which is initially prepared in the ground or thermal states of the quantum spin chain, the power extracted via local external magnetic field is higher for the interacting models than the non-interacting ones. In particular, we illustrate the usefulness of interacting Hamiltonian by considering the ground state of the transverse XY and the XYZ model with magnetic field as the initial state of the battery. We observe that performance of the battery in terms of producing power declines with the increase of $\gamma$. Specifically, the best model which demonstrates the maximum efficiency is the transverse XX model. Although the natural intuition tells us that the performance of a device can decline with the increase of temperature, we find that the suitable tuning of system parameters leads to a scenario where maximal power generation is higher with the initial state prepared at finite temperature than the state with absolute zero-temperature . Finally, we report that impurities help to improve the generation of quenched averaged power from the battery build up by using the ground state of the XYZ model with random couplings either in the $xy$-plane or in the $z$-direction in comparison with the ordered systems – a phenomena known as disorder-induced order. Both the presence of impurities and finite temperature are unavoidable in experiments. Hence the enhancement obtained in both the cases indicate that the implementation of the battery is possible even when the control over the system is not adequate.
